Volume 322 No.6074 3-9 July 1986 £1.90

OCEAN-FLOOR ECOLOGY

AUTHOR INDEX-

CUR-HOG856-313-RP440

Author Index for Volume 322

July — August 1986

Issue no.	Issue date	Pagination
6074	3 July	1-96
6075	10 July	97-194
6076	17 July	195-292
6077	24 July	293-392
6078	31 July	393-484
6079	7 August	485-580
6080	14 August	581-670
6081	21 August	671-758
6082	28 August	759-854

Abe, Y. See under Matsui, T., 322, 526

ns, R.J. Propulsion of organelles isolated from along actin filaments by myosin-I (with Pollard, T D) Letter to re, **322,** 754

Adler, K. Editor, The Encyclopaedia of Reptiles and Amphibians, Book review by Crothers, J. 322, 416

Agnew, W.S. Neurochemistry; Lessons from large molecules, News and views, 322, 770

ayo, J B. Nuclear magnetic resonance imaging of a single cell (with Blackband, S J, Schoeniger, J, Mattingly, M A, Hintermann, M) Letter to Nature, 322, 190 Akhtar, D. See under Rajasekharan, K., 322, 528

Aksu, A.E. See under Macko, S.A., 322, 730

Aktories, K. Botulinum C2 toxin ADP-ribosylates actin (with Bariann, M. Ohishi, I., Tsuyama, S., Jakobs, K.H., Habermann, E.) Letter to Nature, 322, 390

Albert, V.R. See under Nelson, C., 322, 557

Alexander, W. See under Neison, C., 322, 337

Alexander, B. See under Smith, R. A., 322, 722

Alexandropoulos, N. G. Chernobyl fallout on loannina, Greece (with Alexandropoulos, E., Kotsis, K. T. Theodoridou, I.) Scientific correspondence, 322, 779

Alexandropoulos, T. See under Alexandropoulos, N. G., 322, 779

Alexandropoulos, K. See under Varotsos, P., 322, 120

Allaby, M. Editor, The Oxford Dictionary of Natural History, Book review by Fitter, A. 322, 23

Allen, J R L. Book review of Coastal and estuarine sediment dynamics (by Dyer, K.R.) 322, 318

Alley, R.B. See under Blankenship, D.D., 322, 54

Deformation of till beneath ice stream B, West Australia (with Blankenship, D D, Bentley, C R, Rooney, S T) Letter to Nature, 322, 57

Aloisi, M. See under Salviati, G., 322, 637

Alpert, J.C. See under Stolarski, R.S., 322, 808 See under Stolarski R.S. 322, 808

rt, S. See under Lacey, M., 322, 609

Alt, F W. Antibody diversity; New mechanism revealed, News and views, 322, 772

See under Bank, L., 322, 179

ier, R. See under Kachar, B., 322, 365

Alurkar, S.K. Radio observations of PKS2314+03 during occultation by comet Halley (with Bhonsle, R V, Sharma, A K) Letter to iture, **322**, 439

brose, S H. See under Giles, E., 322, 21

Anagasstopoulos, D. See under Alexandropoulos, N.G., 322, 779

Anderson, A. Biotechnology: UNIDO centre taking shape, News,

Strategic Defense Initiative: Britain wins first big contracts, News,

UK science: Save British Science takes off, News, 322, 9

Nature conservation; Too many of the wrong trees?, News, 322,

ation technology: Where next for Alvey?, News, 322, 105 Energy: Power from the Severn waters, News, 322, 202 Getting tough on doctorates, News, 322, 298

UK universities: Research gradings stir emotions, News, 322, 299 UK research grants: Research board pleads for more, News, 322,

New career for Sydney Brenner, News, 322, 397

High-technology trade: Anger over supercomputer veto, News,

Inventors' rewards, News, 322, 487

Plant research: Success breeds privatization, News, 322, 491 Timber trade: A little hope for tropical forests, News, 322, 493 UK Universities; Government yields just a little, News, 322, 764 on, D M. See under Binder, B J., 322, 659

derson, J.A. Neural models: Networks for fun and profit, News

Anderson, R.M. Rabies control: Vaccination of wildlife reservoirs. News and views, 322, 304

Andrews, J. Book review of The Sparrowhawk (by Newton, 1,) 322,

bault, L. P. See under Pakull, M.W., 322, 511

Angel, J R P. A space telescope for infrared spectroscopy of Earthlike planets (with Cheng, A Y S, Woolf, N J) Letter to Nature, 322, 341

Aota, S-i. See under Ohyama, K., 322, 572

Appleby, J.F. See under Diner, D.J., 322, 436

Appleby, P.G. See under Jones, G.D., 322, 313

Argenbright, L. W. See under Doherty, J.B., 322, 192
Argyle, B. RGO move OK (with Jenkins, C. Jones, D. Laing, R. Marsh, T. Martin, B. Murdin, P. Pettini, M. Schild, H. Taylo

K, Terlevich, R, Tritton, K, Wall, J) Correspondence, 322, 402 Arp, H. Recent discoveries of a supermass in the Universe, Scientific correspondence, 322, 316

Ashe, B M. See under Doherty, J B., 322, 192

Ashmore, J F. Ionic basis of membrane potential in outer hair cells of guinea pig cochlea (with Meech, R W) Letter to Nature, 322, 368

Ashtekar, A. Book review of Spinors and space-time. Vol. 2 Spinor and twistor methods in space-time geometry (by Penrose, R. Rindler, W.) 322, 318

orth, A. Disease gene relationship seen (with Shephard, E.A., Phillips, J R) Scientific correspondence, 322, 599 ich, I. See under Forsyth, D A., 322, 349

Atkins, PW. Book review of The unfinished Universe (by Young, L. B.) 322, 122 Atkinson, D.E. Frequency of dizygotic twinning, Scientific corres-

pondence, 322, 780

Attileid, J.P. Structure determination of a CrPO₄ from powder synchrotron X-ray data (with Sleight, A.W., Cheetham, A.K.) Letter tò Nature, 322, 620

Aubert, C. See under Hauser, S.L., 322, 176

Auer, H E. The mechanism of activation of porcine pepsinogen (with

Glick, D M) Matters arising, 322, 664

Awad, J. See under Festenstein, H., 322, 64 Axon, D.J. See under Bailey, J., 322, 150

Bachner, R L. See under Royer-Pokora, B., 322, 32 Bailey, J. Infrared polarimetry of the nucleus of Centaurus A: the nearest blazar? (with Sparks, W B, Hough, J H, Axon, D J) Letter to Nature, 322, 150

Bains, W. Legal problems of Huntington's chorea tests, Scier correspondence, 322, 20

Baker, DG. Visual observation of lightning propagation (with Baker-Blocker, A) Scientific correspondence, 322, 215

Baker, E.T. See under Cowen, J.P., 322, 169
Baker-Blocker, A. See under Baker, D.G., 322, 215

Balmain, A. See under Quintanilla, M., 322, 78 ore, D. See under Weinberger, J., 322, 846

Bank, I. A functional T3 molecule associated with a novel heterodia er on the surface of immature human thymocytes (with De-Phinho, R A, Brenner, M B, Cassimeris, J, Alt, F W, Chess, L) Letter to Nature, 322, 179

Barnt, C. See under Laros, J G., 322, 152

Barker, P.L. See under Doherty, J.B., 322, 192
Barkew, D.J. Continuous flow and discontinuous protein antigenic determinants (with Edwards, M.S. Thornton, J.M.) Letter to Nature, 322, 747

unn, M. See under Aktories, K., 322, 390

Barnes, G L. Archaeology: Japanese agricultural beginnings, News and views, 322, 595

Barnett, J A. The stability of biological nomenclature: yeasts, Scien-

tific correspondence, 322, 599

rrett, D. See under Wasielewski, M.R., 322, 570

Bartelmie, R.J. See under Duncan, R.A., 322, 534 Barthelmie, R.J. See under Davies, T.D., 322, 359

Bartlett, P. See under Cohen, J., 322, 465

za, R. See under Langmuit, C.H., 322, 422

Battarbee, R.W. See under Jones, V.1., 322, 157

Bauer, F W. See under Micr. P.D., 322, 504

Baxter, C S. High-resolution lattice imaging reveals a 'phase trans tion' in Cu/NiPd multilayers (with Stobbe, W.M.) Letter to Nature, 322, 814

ardsley, T. US research: Campus bonanza from the military, News, 322, 4

Scraping the barrel, News, 322, 4

Others have problems too, News, 322, 99

US nutritional research: Your grant is what you eat, News, 322, 104 Genetic engineering: Hepatitis vaccinewins approval. News. 322,

Biotechnology: Regulations please nobody, News, 322, 398 Science Digest dies, News, 322, 401

US budget: Winners and losers worry about Gramm-Radman News, 322, 487

Technology journals: Time to learn Japanese, News, 322, 486 NASA: US space station heads for deep freeze, News, 322, 583

Guatemala accused of political killings, News, 322, S88 Hubble space telescope: Every delay has a silver lining, News, 322,

Weight problems, News, 322, 589

See under Palca, J., 322, 761

Space station; Taming the last lawless frontier, News, \$22,764

Bechtold, R. Directional electron transfer in rathenum-modified horse heart cytochrome c (with Kuehn, C. Lepre, C. Isied, § S) Letter to Nature, 322, 286

cke, M. See under Preisinger, A., 322, 794

See under Preisinger, A., 322, 794

cher, A. See under Squire, J., 322, 555

Begelman, M C. Cooling flows in ellipticals and the nature of radia galaxies, Letter to Nature, 322, 614

Behike, M A. Alternative splicing of murine T cell recepts. β-chain transcripts (with Loh, D Y) Letter to Nature, 322, 379

Bellugi, U. See under Damasio, A., 322, 363

nt, J W. Expression of human adenosine deaminuse in marine haematopoietic progenitor cells following retrovirui transfer (with Henkel-Tigges, J., Chang, S.M.W., Wager-Smith, K., Kellems, R.E. Dick, J.E., Magli, M.C., Phillips, R.A., Bernstein, A. Caskey, C.T.) Letter to Nature, 322, 385

der, J.F. See under Langmuir, C.H., 322, 422 Bender, TP. See under Dmitrovsky, E., 322, 748

Bentley, C B. See under Blankenship, D D., 322, 54 Bentley, C.R. See under Alley, R.B., 322, 57

Berland, J-P. Breeders' rights and patenting life forms (with Lewontin, R) Commentary, 322, 785

an, T. GAP protest over South Africa. Correspondence, 322. 402

n, A. See under Belmont, J.W., 322, 385

Berry, R J. What to believe about miracles, Commentary, 322, 321

Berry-Lowe, S. See under Schön, A., 322, 281

Bertaux, J.L. See under Morcels, G., 322, 90 chart, B. See under Jenni, 1... 322, 173

isle, RV. See under Alurkar, SK., 322, 439

chi, U. A new term in the global carbon balance (with Musi. L. Picardi, M. Piovano, E) Scientific correspondence, 322, 19

ia, E. See under Salviati, G., 322, 637

Bidaux, P. See under Drogue, C., 322, 361

Billon-Galland, M A. See under Lefevre, R., 322, 817

```
Binder. B J. Green light-mediated photomorphogenesis in a dinof-
    lagellate resting cyst (with Anderson, D M) Letter to Nature,
    322, 659
```

d, A P. See under Brown, W R A., 322, 477

Bird, R J. Is cannibalism all in the mind?, Scientific correspondence, 322, 20

Blackband, S.J. See under Aguayo, J.B., 322, 190

Blackett, N.M. Diversity of haematopoietic stem cell prowth from a uniform population of cells (with Necas, E, Frindel, E) Matters arising, 322, 289

nt. JE. See under Moreels, G., 322, 90

recombinant vaccination of the fox against rables using a live recombinant vaccinia virus (with Kieny, M.P. Lathe, R. Lecocq, JP, Pastoret, PP, Soulebot, JP, Desmettre, P) Letter to Nature 322, 373

ik, JL. See under Desjardins, C., 322, 172

bin. D D. Seismic measurements reveal a saturated norous layer beneath an active Antarctic ice stream (with Bentley, CB, Rooney, ST, Alley, RB) Letter to Nature, 322, 54 See under Alley, R.B., 322, 57

ne R. P. See under Moulin R 1 322 450

m, J. Geomagnetic reversals: Evidence for asymmetry and fluctuation. News and views. 322, 13

etti, E.A. Characteristics of Chernobyl radioactivity in Tennes see (with Brantley, J N) Scientific correspondence, 322, 313
sey, R J. See under Doherty, J B., 322, 192

lott, M H P. See under Ussami, N., 322, 629

ger, H. Hopping Conduction in Solids, Book review by Rosseins

eret, L. See under Dejean, A., 322, 70

sa, G S. Geophysics: A paradigm shift in glaciology?, News and views, 322, 18

rke, J.B. Editor, Lindow Man: The Body in the Bog, Book review Molleson, T. 322, 602

rae, WRP, Henderson Island (with David, ACF) Correspond ence, 322, 302

Brable, M. See under Hauser St. 322, 176

mmer, W. J. Editor, Cloning Vectors: A Laboratory Manual, Book review by Harris, T. 322, 603 atley, J. N. See under Bondietti, E. A., 322, 313

eur, G. See under Keating, G M., 322, 43

Bray, W. Book review of American Archaeology Past and Future: A Celebration of the Society for American Archaeology 1935-1985 (Metizer, D J, Fowler, D D, Sabloff, J A editors) 322, 784

ok, J. AGS vindicated (with Dunsmuir, P. Lindemann, J. Suslow, T. Warren, G) Correspondence, 322, 494

er, M B. Identification of a putative second T-cell receptor (with McClean, J, Dialynas, DP, Strominger, JL, Smith, JA, Owen, FL, SeidmanSeidman, JG, Ip, S, Rosen, F, Krangel, M S) Article, 322, 145

See under Bank, I., 322, 179

combe, P. See under Davies, T.D., 322, 359

on. F H. See under Designdins, C. 322, 172

Brookfield, JFY. See under Jeffreys, A.J., 322, 290 Brooks, R.R. See under Lichte, F.E., 322, 816

othwell, D. Editor, Lindow Man: The Body in the Bog, Book review by Molleson, T. 322, 602

own, F.H. See under Walker, A., 322, 517

Brown, K. See under Ouintanilla, M., 322, 78 wn, T. See under McCall, M., 322, 661

wa, W R A. Long-range restriction site mapping of mammalian genomic DNA (with Bird, A P) Letter to Nature, 322, 477

mell, W E. See under Kachar, B., 322, 365 ming, K A. Meteorology: European collaboration on dynamic

atmospheric fronts (with Hoskins, B J, Jonas, P R, Thorpe, A J) News and views, 322, 114

wastein, M. J. Book review of Neurobiology of Vasopressin (Ganten, D, Pfaff, D editors) 322, 25

Book review of Vasopressin (Schrier, R W editor) 322, 25

Brunet, J-F. The inducible cytotoxic T-lymphocyte-associated gene transcript CTLA-1 sequence and gene localization to mouse chromosome 14 (with Dosseto, M, Denizot, F, Mattei, M-G, Clark, W R, Haqqi, T M, Ferrier, P, Nabholz, M, Schmitt-Verhulst, A-M, Luciani, M-F, Golstein, P) Letter to Nature,

Brvce, M. Chiral chemistry; Asymmetric epoxidation gives organic ists a hand, News and views, 322, 776

Bryskin, V V. Hopping Conduction in Solids, Book review by Ros seinsky, D.R. 322, 220

ton, A. Sequences similar to the I transposable element in volved in I-R hybrid dysgenesis in D. melanogaster occur in other Drosophila species (with Simonelig, M, Vaury, C, Croza-tier, M) Letter to Nature, 322, 650

rke, B F. Detection of planetary systems and the search for evidence of life, Letter to Nature, 322, 340

Burks, JS. See under Hauser, SL., 322, 176

Burne, J.F. See under Cohen, J., 322, 465

Cairns, P. Intermolecular binding of xanthan gum and carob gum (with Miles, M J, Morris, V J) Letter to Nature, 322, 89

ack, R. Nitrogen fixation: A role for vanadium at last, News and views, 322, 312

mpbell, K. See under Sodroski, J., 322, 470

Canton, M. See under Squire, J., 322, 555 Carlson, T A. Apparent eukaryotic origin of glutamine synthetase II from the bacterium Bradyrhizobium jap K) Letter to Nature, 322, 568 onicum (with Chelm, B

Case, M. Physiology: Chloride ions and cystic fibrosis, News and views, 322, 407

Case, T J. Editor, Community Ecology, Book review by Townsend,

Caskey, CT. See under Craigen, W J., 322, 273 See under Belmont, J.W., 322, 385

Cussell, P. See under Festenstein, H., 322, 64

Cassimeris, J. See under Bank 1, 322, 179

Custellucci, V F. See under Goelet, P., 322, 419

Casu, B. Controversial glycosaminoglycan conformations (with Choay, J. Ferro, D R. Gatti, G. Jacquinet, J -C, Petitou, M. Provasoli, A. Ragazzi, M. Sinay, P. Torri, G) Scientific correspondence, 322, 215

Cech, TR. See under Garriga, G., 322, 86

Cervetto, L. See under McNaughton, P A. 322, 261

Chadelle, J.P. See under Valladas, H., 322, 452 Chakrabarti, S. See under Chin. V T 322, 441

Chambon, G. See under Laros, J G., 322, 152

Chandler, G O. See under Doherty, J B., 322, 192 Chang, S M W. See under Belmont, J W., 322, 385

Chang, Z. See under Ohvama, K., 322, 572

Chantler, PD. Muscle contraction: Through thick and thin, News and viewe, 322, 498

Charles, S W. See under van Wonterghem, J., 322, 622

Chase, C.G. See under Norman, S.E., 322, 450

Chau, C Y. See under Hard, T M., 322, 617

Cheetham, A K. See under Attfield, J P., 322, 620

Chelm, B K. See under Carlson, T A., 322, 568 Cheng, A Y S. See under Angel, J R P., 322, 341

Cheng, Y. The Geology of China, Book review by Sengor, A M C ..

Chess, L. See under Bank, L., 322, 179

Chiu, Y T. Imaging the outflow of ionospheric ions into the magne tosphere (with Robinson, R.M., Swenson, G.R., Chakrabarti, S. Evans, DS) Letter to Nature, 322, 441

Chony, J. See under Casu, B., 322, 215

Chamet, S. Soviet computers, Correspondence, 322, 204

Church, T M. See under Cutter, G A., 322, 720

Churchwell, E.B. See under Hollis, J.M., 322, 524

Clairemidi, J. See under Moreels, G., 322, 90 Clark, W.R. See under Brunet, J.F., 322, 268

Clarke, R. J. Transform Coding of Images, Book review by Hawkes, P 322, 787

Clegg, J.B. See under Wainscoat, J.S., 322, 21

Coakley, A.J. See under Mountford, P.J., 322, 600

Coan, E.J. See under Herron, C E., 322, 265 Coffey, D.S. See under Nelson, W.G., 322, 187

Cohen, J. Retinal ganglion cells lose response to laminin with maturation (with Burne, J.F., Winter, J., Bartlett, P) Letter to Nature, 322, 465

Cole, F.S. See under Royer-Pokora, B., 322, 32

Coley, P.D. See under Salo, J., 322, 254 Colin, C. See under Weisberg, R.H., 322, 240

CONVENIENT-INFORMATIVE-TIMELY-PROVOCATIVE

FOUR DYNAMITE REASONS WHY YOU SHOULD SUBSCRIBE TO BIO/TECHNOLOGY NOW . . .

You'll save time. Because you don't have time to read every journal in the field. **BIO/TECHNOLOGY** is written and edited to give you all the information you need in ONE convenient source. BIO/TECH-NOLOGY is the only journal to give you news. Features. Original research. Product evaluations. Industrial applications, Job openings, Book and product reviews. And more, If it's important to your work. you'll find it between the covers of BIO/TECHNOLOGY.

You'll learn new ways to im-**L** prove your on-the-job skills and run a more successful operation. Each month BIO/TECH-NOLOGY gives you the scoop on invaluable start-up information...the latest instrumentation...marketing breakthroughs . . . funding sources...new technologies... patents and licences...profiles on how others are avoiding the pitfalls and reaping the rewards. In fact, just one practical tip from BIO/-TECHNOLOGY can be worth many times the cost of your subscription.

You'll be up-to-date on all major industry developments. With correspondents all over the world, BIO/TECHNOLOGY delivers the inside story on who's doing what, where. You'll get the latest word on changing government regulations and tax law, and how they affect your work.

Plus you'll read original research papers by bench scientists, engineers, and biologists that will help keep you in the forefront of every new discovery worth knowing about.

You'll get new ideas you can put to use immediately.BIO/-TECHNOLOGY lets you rub elbows with eminent scientists, tour new facilities and learn how new processes work in every field from genetic engineering to molecular biology. Each month, BIO/TECHNOLOGY helps spark ideas for your own research, for new industrial applications and for getting along in the increasingly competitive financial arena.

If you're not already subscribing to BIO/TECHNOLOGY, don't delay the moment any longer - return the coupon below and we will send you twelve issues. You risk nothing. If for any reason BIO/TECHNOLOGY doesn't live up to your highest expectations, just let us know and you'll receive a full refund on all unmailed copies. Remember too, that your subscription may be tax deductible.

TO START RECEIVING YOUR SUBSCRIPTION, FILL OUT THE COUPON BELOW AND RETURN WITH PAYMENT TO:

innaralo adiminara ensaler sensilivity

Zeta-Probe membranes exhibit the unique quality of binding DNA in alkaline solution. There's no need for pre-transfer denaturation and neutralization steps. Eliminating these steps results in significantly improved resolution!

In conventional Southern blotting, pre-transfer neutralization can lead to partial renaturation. Alkaline transfer insures that DNA is bound and quantitatively fixed in a denatured state. This eliminates another step-post-transfer UV fixation. Because base fixed DNA is more hybridizable than UVfixed DNA, detection sensitivity is greater.

Successful alkaline Southern blotting is strongly dependent upon using the proper nylon-based blotting membrane. Zeta-Probe membranes are the perfect choice. They are well characterized quaternary amine-derivatized nylon membranes, widely used for nucleic acid blotting.

nature

NATURE VOL. 322 3 JULY 1986

A close-up of corals, sponges and other suspension feeders on the Jasper Scamount — a 3.5-km-high extinct volcatio built on the Pacific floor at a depth of 4.200 m some 550 km southwest of San Diego, California. Little is known about deep-scamount faunabut on page 59 of this issue the rich coral community of Jasper Scamount is described. Analysis of populations of deep-sea suspension feeders could provide a measure of the average physical conditions at deep hard-bottom sites. The cover photo was taken by the Deep Tow instrument of Scripps Institution of Oceanography. In the centre is the 16-cm-diameter strobe.

New from Beckman

The Most Advanced Robot To Enter The Laboratory

The Biomek™ 1000 Automated Laboratory Workstation. It's a new concept in laboratory automation, and it's changing the way researchers spend their time.

Ideal for immunoassays such as ELISA, hybridoma screening and selection, or other bioassays, Biomek takes over all liquid handling steps. Pipetting, diluting, dispensing, plate washing, even photometry can be completed at this single workstation.

Fast

With Biomek™ 1000, plate-

 With the Biomek™ 1000 Automated Laboratory Workstation, you can use the labware you're accustomed to.

Complex procedures, from pipetting through photometry, can be performed at this single workstation. based enzyme immunoassays, from sample transfer to OD measurement, can take just 12 minutes, excluding incubations. And a tenfold, 96-tube serial dilution and transfer, with tip changes, can be completed in just over 3 minutes.

Flexible

With Biomek™ 1000, you're not restricted to a manufacturer-supplied program. Biomek does your work the way you want it done. A proprietary assay language lets you easily program methods from simple to complex. And you can use labware you're accustomed to: multiwell plates,

cryovials, tubes, or our new modular reservoirs.

As cost and labor savings become more critical to the research lab, the demand grows for instruments that speed research and stretch research dollars. Biomek 1000 does both.

To find out more, call toll-free (800) 742-2345, or write to Beckman Instruments, Inc., Spinco Division, 1050 Page Mill Rd., Palo Alto, CA 94304. Offices in major cities worldwide.

NATURE'S GUIDE TO HOW BRITAIN RUNS ITS SCIENCE

Nature's practical and useful wallchart has now been thoroughly updated. It provides a complete survey of the administration of British science, showing the functions, key personnel and finance of

- Government departments
- Public and independent bodies
- Research councils

Easily carried to meetings or hung as a wall poster for permanent reference, the new Nature wallchart is an ideal source of reference.

THE DAWN OF A NEW Z

Whenever Zeiss has turned its hand to the very fundamentals of microscopy, microscopy has changed.

In 1846 and the years following, the reputation of the Carl Zeiss workshop was established, based upon microscopes of unparalleled mechanical precision, optical quality and reliability.

In 1866 Ernst Abbe, working with Zeiss, formulated his "Theory of Image Formation in the Microscope", which made possible the series production of high-quality microscopes.

In ensuing decades, Zeiss has pioneered many of the major advances in microscope production and technique.

Now in 1986, a further chapter in the history of Zeiss Microscopy begins: Zeiss presents microscopes with entirely pay infinity corrected

NATURE VOL. 322 3 JULY 1986

Compromise on arms control?

Recent noises from the United States and the Soviet Union suggest that the prospect of a deal on arms control may be more immediate than it has seemed.

More than usual confusion seems to mark the ending a week ago of the latest session of the bilateral talks on arms control at Geneva. On the face of things, President Reagan's declaration that the United States would not necessarily be bound by the SALT II agreement on strategic arms from the autumn of this year made the prospect of an agreement at Geneva less easily attainable than since the negotiations began. Yet Mr Mikhail Gorbachev, the general secretary of the Soviet Communist Party, appears to have sent Mr Reagan a conciliatory letter. coinciding with the summer break at Geneva, whose effect is to suggest that compromise is within the bounds of possibility on the control of weapons of intermediate range in Europe. What is going on? Were the Soviet Union's fierce reactions to Mr Reagan's announcement mere bluff? Or has the Soviet Union been told privately that it is Mr Reagan who was bluffing, and that his threat that SALT II might be abandoned was directed not so much at Moscow as at the hard-liners in Washington?

Enough has now leaked out about the conduct of the Geneva negotiations to sustain a degree of nervous optimism. Mr Gorbachev's message bears on one stumbling block: how to legislate for the complete banning of intermediate-range missiles (SS20 Soviet missiles and the Pershing II and cruise missiles deployed in Europe by the United States) while recognizing that SS20s could be quickly moved from Asia, that the British and French nuclear forces exist and that both sides also have a large number of shorter-range weapons which, if the major Soviet and US missiles were withdrawn, would acquire a strategic significance they now lack? Both sides at Geneva appear to have been captivated by the notion that it would be simplest to do away with all missiles of intermediate range (which, Mr Reagan's "zero option" of 1982, is progress in itself). Mr Gorbachev's suggestion now that compromise is possible suggests the possibility of an agreement on the basis of a sharply reduced but nonzero intermediate force. Few would complain at that.

Much less has been said about progress at Geneva on strategic arms. It would help, of course, if the two sides were merely to agree to limit strategic weapons to the numbers allowed under SALT II (a gigantic 5,000 warheads each) and were to take the opportunity to tidy up the treaty, making it acceptable to the US Congress, but that will not satisfy the aspirations of the rest of the world, while even the negotiators at Geneva appear to think that would be a prize not worth having (which, again, is progress of a kind). The best bet is that a fifty per cent reduction of warheads is attainable now; Mr Gorbachev made an important mark earlier this year with his declaration that even such an agreement could be only an interim measure, a prelude to further more substantial reductions of nuclear arms. The paradox is that, if that principle were accepted by both sides, the degree of reduction agreed in the next few months would be less important, and so would be more easily attained.

The third item on the agenda at Geneva is the most taxing, and that most likely to prevent an agreement being reached: to what extent will the devotion of the US administration to the Strategic Defense Initiative (SDI) stick in the throat of the Soviet Union? Here too, Mr Gorbachev has been making conciliatory noises: if research means only laboratory research, all

well and good. But then, Mr Gorbachev continues (as in his latest letter to Mr Reagan) why should not both sides reaffirm their adherence to the Anti-Ballistic Missile Treaty, undertaking that they will not quit the treaty for, say, 15 years? This position represents a Soviet retreat from the fierce declarations from Moscow in 1983, suggesting that merely toying with the idea of a defence against ballistic missiles was an act of aggression. But it seems improbable that Mr Gorbachev's moderation of the past few weeks suggest he will to let SDI go ahead full tilt.

Fortunately, even here constructive compromises should be possible. First, Mr Gorbachev probably knows as well as anybody of the reluctance of the US Congress to give the project the huge sums of money it has been asking for, implying that decisions about the deployment of SDI will not take place until long after the promised decision time in the early 1990s. Second. it is also well known that there has to be a general election in the United States two years from now, and that a new president (Mr Reagan cannot stand for a third term), whatever his or her political stripe, may not set as much store by the benefits of SDL Finally, however meagre the outlook for this ambitious project. there is no obvious reason why the most likely outcome of this system, an efficient system of early warning based on infrared detectors, should not be welcomed by both sides. That is one sense in which Mr Gorbachev's suggestion that both sides should reaffirm the ABM treaty for 15 years is already a useful compromise. It requires from the United States only that degree of restraint likely to be forced on it by the technological difficulties of this ambitious project and by the increasing scepticism of the US Congress; if the two sides can make some kind of agreement this year, Congress will be even less willing to spend, with the result that the dangerous features of SDI will wither away

So much for the carrots; Mr Gorbachev's stick is the threat that he will not attend a second summit meeting unless there is something substantial about which to agree. Once the summer is over, and the campaign for the mid-term elections has begun, there will be powerful forces in the United States pushing the administration towards some lasting achievement on the international front. To fail to have a summit meeting will seem, or be made to seem, a black mark in the first week in November. Not for the first time, Mr Reagan may find that his natural (and evidently deeply felt) suspicion of arms control agreements will have to be forsaken in the face of the general feeling that there is no more laudable goal. This is the turnabout forced on him during the first year of his administration six years ago.

Research democracy

Moving Greenwich to Cambridge is not the end of the world, but users' voices need to be heard.

How should grant-making agencies manage their relations with those parts of the research community that rely on them for support? That is the question most urgently prompted by the decision of the British Science and Engineering Research Council (SERC) last week that the Royal Greenwich Observatory (RGO) should be moved to Cambridge rather than to

Edinburgh or Manchester.

The decision itself is impeccable, and properly within SERC's gift. SERC decided early in the year that a move was necessary, largely on the grounds that RGO had become a somewhat self-preoccupied institution that would benefit from stronger links with British universities. The managerial case for combining RGO with the Royal Observatory, Edinburgh, SERC's first preference, has been talked down by the British community of astronomers, while the more daring option, that of moving to Manchester, seems to have been abandoned out of deference to those among the RGO staff who believe that life north of the River Trent would be uncomfortable, a little like living in a foreign country. The result is that Cambridge will become both the administrative and academic centre of British astronomy. (Those now working at Edinburgh will increasingly think themselves marooned.)

This prospect is not necessarily bad; Cambridge is an excellent place. SERC also deserves some credit for having made a decision, a decision of any kind. But it has had to do so in the face of a torrent of complaints. Having pulled off this one triumph, SERC should resolve that it will not allow itself to be alienated a second time from those whose interests it exists to foster. This moral needs to be learned elsewhere as well.

Nobody doubts that SERC has the interests of British astronomers at heart. Over the past few years, it has been exceedingly generous towards them. There is now a prospect that British astronomers will have access to optical observing equipment, in the Canary Islands and in Hawaii, relatively more modern than they have enjoyed since, in the eighteenth century, Herschel made his name as a builder of telescopes. So why do British astronomers bite the hand that feeds them so well? Because they have a sense that SERC, acknowledged to be generous, is nevertheless acting high-handedly. It is not so much a benefactor as a nanny who "knows best". Why else does it not publish the two reports on the future of RGO (and Edinburgh) which apparently failed to come to an acceptable conclusion (in the eyes of SERC).

The remedy should be obvious. SERC should devise means by which its constituents can make their needs felt. Traditionally, SERC has delegated this task to the Space, Astronomy and Radio Board, formally taken as representative of astronomers because, in due course, most people of distinction pop up amongst its membership. But this is no longer an acceptable way of dealing with major decisions about the development of new instruments, telescopes in particular. Instead, there should be a committee whose members are not bound by secrecy and which is not forever having to measure its claims on resources by the calculation that rebuffs will diminish its authority in the competition for dwindling resources. Far better that there should be an open independent committee representing astronomers and their interests to which all working astronomers would have access, and able to ask for projects that are occasionally turned down. This is how high-energy physics is dealt with in the United States (see Nature 321, 636; 1986). The system does not rid highenergy physics of frustration, but is makes decisions intelligible.

How would such a system work in Britain, where restraints on public discussion seem all too natural? As things are the best lightning conductor for the opinions of the users of SERC's generously equipped new observatories would be a committee organized by the Royal Society or on some other independent base whose job would be the definition and repeated redefinition of researchers' needs. It would remain for SERC to decide how its facilities should be managed, which is its proper function. While about the job of setting up this mechanism, the research councils should also pay attention to the needs of other disgruntled parts of the research enterprise, the geophysicists, for example. The principle, which applies generally, is that users' needs are not merely useful planning information for managers, but are the only basis on which a sensible programme can be designed.

Eureka discovered

The ministerial meeting of the Eureka project has said all the right things. Does it mean them?

THE European Eureka project, conceived by President François Mitterrand of France as a counter to what seemed the technological threat to Europe of the Strategic Defense Initiative, seems to have taken on a life of its own. The British government, for one, seems to have been converted from scepticism to enthusiasm, at least to judge from the speech at the opening of the third ministerial conference, in London this week, by the British Prime Minister, Mrs Margaret Thatcher. The British government seems to have been persuaded by the experience of the past eighteen months that the Eureka project has not flowered into yet another trans-national bureaucracy in Europe, that there is no danger that it will become a vehicle for other peoples' chauvinism and that it may even be a useful vehicle for urging on faltering Europe some of the policies from which it has consistently shied over recent years. That is more than a little to be grateful for.

Yet Eureka remains a project whose success so far are intangible, and whose promise is hard to pin down. Mrs Thatcher this week repeated the old adage that Britain is strong on discovery and weak in their application. She went on to complain at the tendency of technical people in Europe to disparage the application of good ideas, and to urge that people should pay more attention to the design of products suited to their intended markets. The difficulty with this familiar homily is that, now, it is out of date. Technical people all over Europe would give their eye teeth for the opportunity to design marketable products. They know that nations that fail on that score become impoverished remarkably quickly. The impediments to European prosperity are now more probably structural than psychological.

Structural? When much of Europe is linked together in a community called popularly a "common market"? How can that be? Because the common market is in no real way a common market in the ordinary sense, but rather a loose gathering of ten European nations provided with common (and often irksome) services by a central bureaucracy, with a general understanding that they may discriminate against each other's goods and services only by bureaucratic means and, to the extent that they are united, drawn together by their mutual suspicion of each other as traders. The unexpected success of Eureka, which functions by facilitating but not financing collaborative projects involving European companies and universities on technical projects, is that it has helped in several subtle ways to exorcise this long-standing suspicion.

So where will Eureka lead? Mrs Thatcher was right to insist this week that Eureka by itself is insufficient, and that something has to be done to make the common market genuinely common. But how? Governments' own xenophobia in public purchasing is an obvious place to start (as she said), but governments have been more willing to applaud the abstract principle than to change their own ways. That is why Eureka's well-wishers must also hope to build on the psychological changes now well under way in the informal European community, that in which people enjoy crossing frontiers without formality. One of the missing ingredients of Mrs Thatcher's speech this week was the recognition of the importance of the educational system, and especially of European universities, in providing the cultural cement that will, given encouragement, turn into economic cement as well. For, when everything has been said about the need that Europe should be more conscious of markets in Europe and elsewhere, it remains the case that Europe is dangerously short of the skills needed to carry out that task. Eureka may be working well so far, but its further success will only serve to draw attention to the urgent need for a coordinated system of higher education and research. This will be a great opportunity, but will at first be seen as a threat to national integrity.

West German space research

Hermes causes sacking and cabinet unrest

Hamburg

A ROW over the West German space programme has resulted in the sacking of the head of the Department for Space Affairs. Aeronautics and Traffic Research. Wolfgang Finke, a Social Democrat, was removed from the post he has held for 13 years by the Minister of Research and Technology, Heinz Riesenhuber, a Christian Democrat, last week.

The two have disagreed over almost everything: Riesenhuber accused Finke of not having done enough for the ocean research programme; Finke in turn opposed his boss's decision to cut traffic research. But the crucial point of their disagreement reflects a political quarrel within the coalition cabinet over West German participation in European space programmes and, in particular, over participation in the French Hermes space shuttle project.

Like some ministers, Finke has fought for "stronger engagement for an independent European space potential that represents our political importance, our economic capacity, and technical knowledge".

Riesenhuber, however, is against a European space adventure. He has already agreed to cooperate in the construction of the Ariane 5 rocket, under French management, and to join with the United States to build the space station Columbus, at a cost for West Germany of DM 4 million. But two years ago he rejected France's offer of a share in the development of Hermes because of doubts over costs.

The French estimate of a total cost of DM 6,600 million was referred to as "total nonsense" by the minister, who considers that the worldwide satellite system necessary for the control and supervision of the space shuttle will alone cost at least DM 6,600 million. And he is very much aware of the words of Gerhard Stoltenberg, Minister of Finance, who announced to the cabinet in June last year that there was to be no money for Hermes or similar big projects. Before he is willing to reconsider his position, Riesenhuber wants a more realistic calculation of the likely costs.

On the other hand, Chancellor Helmut Kohl, another Christian Democrat, supports cooperation with France in general, and Foreign Minister Hans-Dietrich Genscher, of the Free Democrats, is urging his colleagues to back Hermes. The two—among others—have been influenced by a report published last week by the Research Institute for Foreign Policy, in which support is demanded for both

Hermes and a European space station. One of the authors of the paper is none other than fired Wolfgang Finke. It appears that Finke had told Kohl that he had his chief's support for the report — without the latter's knowledge. Riesenhuber thus had no choice but to sack him.

On balance there remains lukewarm support for the Hermes project within the cabinet. But questions over real costs and the extent of French domination of the project will need to be answered before any real commitment is forthcoming.

Jürgen Neffe

Hermes limps on to ESA's agenda

WEST Germany gave a grudging commitment last week to go ahead with "preparatory studies" for a possible European space shuttle, Hermes, despite the sacking of the official responsible for coordinating Germany's space policy (see above).

However, the agreement last week by all 13 member states of the European Space Agency (ESA) that Hermes, so far only a French project, should be thus "Europeanized", falls far short of a total commitment to build a shuttle.

No money has yet been committed, but in three months, at the October meeting in Paris of the ESA council, states will be expected to make a declaration of what share they will take of a 48-million-ECU (European Currency Unit) nine-month detailed analysis of the real costs, benefits and likely technical problems of building Hermes

ESA officials believe that the commitments made in October to this £32-million preparatory programme should be a "good indication" of likely future national involvement in the full construction of the space plane. However, a spokesman for the West German research ministry, BMFT, took time off from a European technology conference in London on Monday to say that German estimates of the true cost of Hermes were "five to six times" the £1,500 million or so suggested by the French. Moreover, the spokesman said, the German research minister, Heinz Reisenhuber, had told his British opposite number, Geoffrey Pattie, that Germany backed the British alternative project, "Hotol", a project for a horizontal take-off, partly air-breathing space-plane. "Hermes is old technology", the spokesman said. "Hotol is the future". Robert Walgate

Biotechnology

UNIDO centre taking shape

An international biotechnology centre for the developing countries came a step closer to realization last week with the appointment of its first director. Professor Irwin Gunsalus, emeritus professor at the University of Illinois, was chosen to head the International Centre for Genetic Engineering and Biotechnology (ICGEB) at a meeting organized by the United Nations Industrial Development Organization (UNIDO).

Five years have passed since the idea of a centre to bring the benefits of biotechnology to the developing countries was first proposed. During that time, many scientists, recognizing that there is a void in knowledge of molecular genetics and recombinant DNA technology in these countries, have given the centre their blessing. Now, UNIDO has provided funding to employ Gunsalus for three years, during which time he will recruit the scientists and technical staff needed to make the centre operational. He will also have to try to raise funds for the centre, which is not expected to be easy.

Italy has so far been generous in supporting the scheme and one of the centre's two branches is planned for Trieste. The other is to go to New Delhi. Rapid progress is unlikely, for almost all of the 37 countries that have signed up to support the centre are from the developing regions of Africa, South America, the Caribbean and Asia and are not easily able to provide money. The major industrial European countries, the United States and Japan have yet to support the centre and may well not do so until they have a chance of seeing how successful it will be.

Control of the centre is intended to remain within the developing countries so they can be confident that it is not just a route by which their best researchers can vanish to the advanced nations. Indeed, it is hoped that the flow will be in the opposite direction, with researchers from the advanced nations taking visiting fellowships at the centre. It is planned that each will have a staff of 30 scientists, 20 post-doctoral students and 40 technicians. Many of the staff will be on 2-3 year appointments.

Running the pair of institutes is not going to be easy. In theory, with the developing countries' heavy dependence on agriculture, biotechnology should bring enormous benefits. But much basic research on tropical agriculture remains to be done and the institutes will need to stimulate such research, at the same time fighting off demands for rapid returns on investment.

Alun Anderson

Campus bonanza from the military

Washington

US SECRETARY of Defense Caspar Weinberger last week announced the first round of winners in a \$110 million bonanza designed to improve universities' military research capabilities. The University Research Initiative (URI) will support 86 research projects at 70 institutions with awards ranging in value between \$170,000 and \$3 million.

The projects supported cover a wide spectrum. Most are intended to bring together small groups of researchers from different disciplines. But funds will also be set aside for instrumentation and for fellowships designed to encourage exchanges between universities and other institutions, especially the Department of Defense (DoD)'s own laboratories. Awards are conditional upon the successful conclusion of negotiations between DoD and the institutions.

The universities' enthusiastic response to URI seems to suggest that sensitivity on campus to military research has all but vanished. According to Dr Ronald Kerber, deputy under secretary of defence for research and advanced technology, most of the 963 URI research proposals received were of strikingly high quality. Kerber sees the large number of proposals received — worth nearly \$6,000 million in funds - as confirming universities' willingness to conduct basic research of possible military interest. Kerber said there had been no evidence of boycotts by academics opposed to the growth in the defence research budget.

Awards are typically in the \$1 million—\$2 million range, less than the \$4 million originally expected. That, Kerber explains, was partly to prevent faculty from "building empires". A single faculty member can be well supported with about \$200,000, so the average group will be of between five and ten researchers. Several awards will go to consortia of two or more universities.

Awards were made on the basis of competitive review by DoD scientists, helped by some outside consultants. As expected, most go to materials science and electronics.

Composite materials and electronic control dominate; there is also special emphasis on artificial intelligence, robotics, biotechnology, oceanography, hydrodynamics and biological structures. The awards, lasting 3–5 years, will be made through the Army Research Office, the Office of Naval Research, the Air Force Office of Scientific Research and the Defense Advanced Projects Research Agency.

The awards are still conditional upon availability of funds in DoD's budget for

fiscal year 1987, but Congress has so far strongly supported URI, providing funds beyond those requested. The first URI round comes out of 1986 and 1987 funds; the next round will not be until 1988. All URI projects will be unclassified, and Kerber expects them to remain so.

Tim Beardsley

Scraping the barrel

Washington

IRONICALLY, on the day that US Secretary of Defense Caspar Weinberger announced the first competitive awards to be made under DoD's new University Research Initiative, the Senate finally gave in to pressure from the House of Representatives to divert \$55.6 million of DoD funds to unreviewed research and construction projects at nine named universities and colleges.

The funds are provided in amendments to an emergency DoD money bill. Ten such "pork-barrel" projects were approved at the end of last year. But as they had not been subjected to peer review, they were opposed by DoD itself, which prefers to make research awards by competitive merit review (see *Nature* 321, 549; 1986).

Several of the universities provided for in the DoD bill employed influential lobbying and public relations companies in Washington to make their case to wavering congressmen. Their task was made easier because federal support for university facilities is generally agreed to be inadequate, and politicians like to be seen appearing to benefit education in their home states.

Two attempts were made in the Senate to block the disputed projects, but the Senate finally voted 56-42 last Thursday to accept a House version of the bill that reinstated nine pork-barrel projects. The Senate Appropriations Committee's report notes, however, that the Senate does not intend to support similar unreviewed projects in future.

The original ten pork-barrel projects in the DoD appropriation bill were reduced to nine last December when Frank Rhodes, president of Cornell University, refused to accept \$10 million that Congress had earmarked for computer research there, unless the project was approved by merit review.

The universities due to benefit from Congress's generosity are: Wichita State (\$5 million); Nevada (\$3.5 million); Oklahoma State (\$1 million); Iowa State (\$6.5 million); Rochester Institute of Technology (\$11.1 million); Syracuse (\$12 million); Northeastern (\$13.5 million); Oregon Graduate Center (\$1 million); and Kansas (\$2 million).

Falkland Islands

Opinions divided on penguin deaths

"NUCLEAR cargo" from the four British ships sunk during the Falklands conflict is polluting the South Atlantic, according to Soviet officials in Buenos Aires. At a press conference called last week to condemn President Reagan's unilateral repudiation of the SALT II agreement, the Soviet representatives claimed that the British military presence in the Falklands was a major threat to world peace, and that "the Argentines now have their own Chernobyl in the Atlantic".

This allegation was said to be based on research by the Buenos Aires correspondent of the Moscow weekly Literaturnarya Gazeta, Mr Vladimir Vesenskii, and on the Spanish newspaper Cambio 16. Vesenskii, the only civilian on the threeman Soviet panel, claimed that all four ships had had nuclear weapons on board and that HMS Sheffield, after being damaged by Argentine bombs, had been sunk by the British themselves "because of the danger of contamination". Vesenskii implied that contamination from these alleged bombs was responsible for the recent appearance of larger numbers of dead penguins "on the Malvinas beaches". Quoting an unnamed Argentine legislator, Vesenskii said that the "outer casings of the nuclear bombs were designed for dry places, not the ocean".

Asked if the Soviet Union had any information proving that there are now nuclear bombs on the Falklands, the Soviet chargé d'affaires Viktor Tkachenko said simply that the Soviet Union and Argentina were "greatly concerned" about the building of a British military base on the islands, and called for Argentine–Soviet military relations to be strengthened at the "non-strategic level".

• Vera Rich
• Results from UK laboratories seem to show that the penguin death-rate, in fact, is considerably worse than Vesenskii implied. He spoke of "tens" of dead penguins being washed up. In fact, from mid-February, elevated death rates of rock-hopper penguins, and, to a lesser extent, gentoo penguins, began to be observed, and on 25 May, more than 3,000 dead rockhoppers were counted in a single rookery on New Island (off West Falk-land).

Three batches of specimens have been spent to the United Kingdom, to the laboratories of the Ministry of Agriculture, Fisheries and Food (MAFF). Preliminary reports indicate that the birds died of starvation. Some appear to have suffered from puffinosis, a viral disease affecting sea-birds, and some show elevated lead levels in liver and kidneys.

Strategic Defense Initiative

Britain wins first big contracts

Britain has become the first foreign country to win a substantial contract for research in the US Strategic Defense Initiative (SDI). On Tuesday last week, George Younger, the Secretary of State for Defence, and Caspar Weinberger, his opposite number in the United States, signed a \$10 million letter of offer and acceptance in Washington. A further \$4.3 million contract goes to the United Kingdom Atomic Energy Authority's Culham Laboratory.

The contracts come at a time when there had been increasing criticism of British failure to obtain funds for research in the SDI programme. As Britain was the first country to back the US "star wars" project and to agree to cooperate on research and development, there were hopes that major contracts would be won —£1,000 million was announced as a possible figure last year by the then Secretary of State for Defence, Michael Heseltine. But there is now little hope that expenditure in Britain will come anywhere near this target.

The \$10 million contract is for a theoretical research study, expected to last 22 months, of the systems "necessary for the integrated defence of Europe". At present, that means the study will give a British view of the defence of Europe; at a later date, European allies may be added to the project. The contract has been put out to tender.

Culham Laboratory's contract is to cover research on neutral-beam particle systems. Neutral-beam weapons could form part of the first layer of an SDI system, shooting down ballistic missiles from space-based platforms. The Culham group, headed by Dr Tom Green, has already built up an international reputation for neutral-beam research. In collaboration with a French group, it designed the neutral-beam injectors for the Joint European Torus (JET) which sits alongside the Culham laboratories. The injectors fire intense beams of very energetic hydrogen and deuterium atoms into the tokamak to help heat up the plasma inside it. To generate the beam, positively-charged ions are accelerated electrostatically: they are subsequently neutralized in a gas cell, as charged particles would not be able to penetrate the intense magnetic field confining the plasma. Neutral beams are also essential for a space-based weapon as charged particles would be sent off course by the Earth's magnetic field. But for SDI application, where very high-energy beams are needed, negatively charged ions will be accelerated and an electron stripped off them before firing - it is here that the Culham group will have to develop new technology.

Any application for neutral beams as weapons is, of course, a long way off. Much basic research remains to be done. But if the present work, to extend over a three-year period, is successful, further SDI contracts may come along. The Culham group has already proved itself to be imaginative in finding research contracts; since the JET work drew to a close it has carried out research on semiconductor ion implantation, tokamak plasma beam diagnostics and ion thruster engines for keeping geostationary satellites on station.

Other SDI projects are rumoured to be in the pipeline for British research groups. The United States is interested in work on electromagnetic guns carried out at the

Royal Armament Research and Development Establishment and it is likely that a contract will be signed in the coming months.

Electromagnetic guns come in two varieties. In a rail gun two rails are bridged by an armature behind a metal protectile. When a current of several million amps is applied the expanding current loop fires the projectile.

Other electromagnetic guns are more similar to a linear induction motor, a series of switched coils induces a current in the projectile to fire it.

Either way velocities in the tens of kilo metres per second can be achieved – a standard army rifle bullet goes at less than a kilometre a second. The aim is for velocities of 50–100 km per sec tor electromagnetic guns which might be based in space or on land.

Alun Anderson

High-energy physics

Supercollider in the balance

Washington

ELEVEN US senators have signed a letter to President Reagan urging him to give his personal support to the Superconducting Supercollider (SSC), the 40 TeV proton-proton collider now at the design stage. Without strong White House support, the senators say the project "cannot go forward".

Already there are rumblings in Congress that the Challenger accident and the Gramm-Rudman deficit reduction act will make it hard to find the \$3,010 million needed to build SSC. The Department of Energy (DoE) steadfastly maintains that it has not decided SSC's future, but construction delays seem likely, and it is just possible that the project may be cancelled.

Senators Barry Goldwater and Dennis DeConcini, both Republicans from Arizona, organized the letter to President Reagan. While the letter describes SSC as "a very important national science project", the senators also find SSC attractive for the 7,000–8,000 jobs and millions of construction dollars it will bring to the state where it is built.

In testimony last week before the Senate Committee on Energy and Natural Resources, Alvin Trivelpiece, director of DoE's Office of Energy Research, called technical progress on SSC "excellent". But Trivelpiece said DoE is still weighing its options. A decision must be made soon so that the department's budget can reach the White House by September. Members of Congress in both the House and Senate feel a full-scale start for SSC in the 1988 budget is unlikely.

The House Appropriations Committee last month removed from the DoE budget request \$20 million that was to be used for continued development of SSC. While the committee's action must still be approved

by the full House, and later by the Senate, it was a signal that Congress is not interested in seeing more money put into SSC until its future is determined.

In May, DoE completed a favourable review of the conceptual design of SSC. The review described the \$3,010 million budget proposed for SSC as "credible and consistent with the scope of the project" The report also called the six-and-a-half-year construction schedule feasible, and said SSC will meet the requirements of high-energy physics "well into the next century".

But SSC's timing may be bad. William Graham still awaits confirmation by the Senate as director of the White House Office of Science and Technology Policy (OSTP). Until he comes on board as director, nobody at OSTP is anxious to carry the torch for such an ambitious project. The retirement of Hugh Loweth from the Office of Management and Budget, after 13 years as head of the Energy and Science Division, may also influence reception of the budget.

Senator Daniel Evans (Republican. Washington), a member of the Senate Energy and Natural Resources Committee, has declined to sign the Goldwater-De Concini letter because he feels it would be irresponsible to commit funds to SSC when Congress is trying desperately to reduce the budget deficit. But he does have a modest proposal for DoE. Evans wants DoE to offer SSC as a "carrot" to the state it chooses for the site of the first deep geological repository for high-level nuclear waste. The three states chosen by DoE as final candidates for the waste storage site, Washington, Texas and Nevada, have so far been less than enthusiastic. All three have gone to court to try to block DoE's plans. Joseph Palca

Depressing news from Paris

Paris

Tin: razzmatazz of last week's international conference on acquired immune deficiency syndrome (AIDS) in Paris was tempered by gloomy facts and figures. Unless some effective form of therapy is found, 179,000 people in the United States will die of AIDS in the next five years; no doubts remain about the heterosexual transmission of the AIDS virus; at least half the members of several groups of intravenous drug users are now infected; the virus evolves as rapidly as the influenza virus; and it already has an alarming hold in some cities in central Africa.

There are still doubts about the validity of some of the African statistics, but those, from Kinshasa, capital of Zaire, are copious and reliable. Of a group of prostitutes, 27 per cent have been infected by the virus as have 6.5 per cent of all the patients in hospital. In Rwanda, the equivalent fig-

Japan's islands coming home

Tokyo

FOR years, the Japanese government has been doggedly trying to get the Soviet Union to return four small islands off the coast of Hokkaido seized in the closing days of the Second World War. Now a new survey shows that some of the islands will return quite soon — geologically speaking, that is.

The islands of Etorofu, Kunashiri, Shikotan and the Habomai group — the "northern territories" — were home to 16,000 Japanese before the Soviet invasion took their troops to an island within 5 km of the shores of Hokkaido in 1945. The continuing occupation is an endless source of friction between the two countries and has prevented Japan from concluding a post-war peace treaty with the Soviet Union, with all the trade benefits that might bring. But it seems the islands are creeping home at the rate of some 2 metres every 80 years.

The figures come from a resurvey of Hokkaido by the mapping division of the Geographical Survey Institute of the Ministry of Construction. A laser range-finder has revealed crustal movement that has occurred since an earlier triangulation survey carried out between 1908 and 1916. Throughout most of Hokkaido, net movement has been of the order of only a few centimetres or tens of centimetres. The two closest islands, the Habomais and Shikotan, are moving very much faster. If things continue as they are, they should collide with the mainland in about one million David Swinbanks vears.

ures are 88 per cent and 18 per cent, with 28 per cent recorded in pregnancy. With similar figures from other countries that border on Zaire, it is clear the virus is very well established and will continue to spread from mother to child and, most importantly, by heterosexual intercourse. That accounts for the approximately equal distribution of infection between the sexes in central Africa, whereas in developed countries male homosexuals still account for about 70 per cent of cases.

In western Africa the situation is less clear and, in many ways, more interesting. There is little, if any, evidence of the presence of HTLV-III/LAV, the standard A1DS virus, but increasing evidence of the distantly related HTLV-IV and LAV-2 viruses. It remains uncertain whether these are two names for the same virus. HTLV-IV was identified in Senegalese prostitutes whose health seems unaffected by the virus. As many as half the prostitutes in one unidentified (for political reasons) country in the region have been infected with HTLV-IV, with 38, 7 and 0 per cent in three nearby countries.

So far, not a single case of AIDS has been recorded in an HTLV-IV infected person, according to Max Essex of Harvard University. On the other hand, LAV-2 has now been isolated by the Pasteur Institute team led by Luc Montagnier from 8 AIDS or pre-AIDS patients from Guinea Bissau, Senegal and Cape Verde Islands, but its prevalence in prostitutes, or in general, is not yet known. There seems to be little prospect of an immediate exchange of material between Essex and Montagnier or, therefore, of establishing the precise relationship of the two viruses.

Hope remains that once the west African and monkey viruses have all been molecularly cloned and compared with HTLV-III/LAV, there will be a clear indication of which DNA sequences are responsible for pathogenicity and might form the best vaccines. Meanwhile, there is steady progress towards trials, perhaps later this year, of whether chimpanzees immunized with vaccinia virus engineered to contain the envelope gene of HTLV-III/LAV will be protected against infection with the virus.

There are, however, distinctly mixed views on the likely success of such a trial without (or even with) refinement of the envelope gene. Furthermore, there is emerging evidence of the rapid evolution of the virus within individuals. Thus Beatrice Hahn of the University of Alabama reported that consecutive isolates of the virus from individual patients had distinctive genetic maps, and comparable differences between the virus from infected blood donors and their recipients were

described by A. Srinivasan of the Centers for Disease Control in Atlanta. Probably both the direct evolution of the virus under pressure to escape the immune system and the emergence of different viruses from a mixed infecting population are involved. The chances of effective vaccination against such a moving target may be slim, as in the case of influenza virus.

For want of anything better as an advance in AIDS therapy, attention (certainly press attention) focused on the partial reconstitution of immune function in one AIDS patient given a bone marrow transplant from his healthy identical twin along with transfers of peripheral lymphocytes both before and after the transplant. But two other identical twins did not respond to the same form of treatment. Anthony Fauci, of the National Institutes of Health, intends to pursue such treatment, assessing the value of transplantation from matched siblings, the frequency of lymphocyte transfers and the value of simultaneous therapy with antivirals.

Little progress with antivirals was reported, although the first results of a double-blind placebo trial of azidothymidine are due this summer. Samuel Broder, of the National Cancer Institute in Maryland, who is persisting with the trial in the face of considerable pressure from some quarters simply to give the drug to all patients, is quietly optimistic about the outcome, particularly as the drug gains access at potentially therapeutic levels to the brain where it may reverse the loss of cognitive functions caused by the virus. Burroughs Wellcome, which makes azidothymidine, has exhausted the world supply of thymidine, from which it is made, but has plans to overcome this problem if the drug is shown to be valuable.

Without effective therapy, progression from infection to disease is not inevitable, but the cumulative incidence of AIDS in some well-studied cohorts of homosexuals is now around 30 per cent and showing no signs of decreasing with time. Moreover, Bob Redfield, of the Walter Reed Army Institute of Research in Washington, reported that 90 per cent of a series of patients who could be classified as belonging to one of 5 stages that precede full-blown AIDS progressed by at least one stage within 18–36 months.

Without an effective vaccine, the only means of prevention is to avoid intimate sexual contact with infected people, and to avoid their blood or blood products. There are clear signs that some homosexual communities have effectively taken this advice to heart. But it is less certain that drug users are doing so. In the worst reported case, 76 per cent of a group of Italian drug takers are now infected, compared with 6 per cent in 1980. In some groups fewer than 10 per cent are yet infected, but the reason for these differences is still unclear.

Peter Newmark

European cooperation

Eureka gets down to business

EUREKA, the long-heralded but somewhat formless European programme of industrial cooperation on high-technology products, came a little more into shape on Monday, with the ministerial conference in London that marked the end of Britain's six-month secretaryship of the programme and the approval of over 60 new projects costing some 2,000 million ECU (£1,300 million).

Industry, it seems, is beginning to take Eureka seriously as a means of developing products -- such as metal-working carbon dioxide lasers and advanced road vehicle guidance and communications systems that can take a slice not only of Europe's market of 400 million consumers but also of the 120 million in Japan and the 240 million in the United States. Governments are involved because they can use their political weight to help remove trade barriers and develop common standards. Already five or six of the projects approved on Monday involve requests for additional political support of that kind, British officials say.

Monday's meeting, opened with evident enthusiasm by British Prime Minister Margaret Thatcher, approved a fivefold increase in the number of Eureka projects since the last ministerial conference in November, and established a significantly tiny secretariat of seven civil servants in appropriately - Archimedes' Street in Brussels. The significance of the size of secretariat was that governments are determined not to create "another bureaucracy" but merely a clearing house for projects proposed by industry itself.

Research is not a problem. Europe's research laboratories "burst with talent and imagination", said Mrs Thatcher, but the old continent fell down in turning this into market success. To change that, Eureka is encouraging companies to share development. But Eureka "was not a source of funds" said Thatcher (this despite the efforts by some smaller countries and Italy to establish a central European funding system for the programme). Rather, Eureka seems set to develop with governments providing support only for their national companies within particular cooperations, a system which will clearly favour the larger countries.

The British government is setting aside no new money for Eureka, but, according to technology minister Geoffrey Pattie, it will find some £10 million a year from within the Department of Trade and Industry's "Support for Innovation" scheme to back the British companies in 28 Eureka projects. These projects, including company and other national support, will account for some £750 million of new technology development over the next | internal memorandum by its office of in- | legal".

five years or so, Pattie indicated. But onethird of the Eureka projects involving Britain have no government support at all. said Pattie. West German government support is said to be on a similar scale. Italian research minister Luigi Granelli said on Monday that he "guaranteed" that every high quality proposal will get government support, but put no scale to funding which must finally pass a sceptical ministry of finance. Italian foreign minister Andreotti also hinted that Italian companies must beef up their proposals: there is no point in getting involved in Eureka "merely as a matter of prestige", he said. Meanwhile, the backing for Eureka in France, where the project originated 18 months ago, remains strong politically but uncertain financially, in a country which recently slashed its research and technology spending. Other countries, a total of 19 in all, including Iceland which joined on Monday, plan backing in proportion to the interest of their national companies.

Monday's meeting promised clarifica-

tion of one long-standing issue, the relationship of Eureka to the European Commission's own international research and development programme. According to Pattie, who for the next six months, which mark Britain's presidency of the European Council of Ministers, will chair the council of research ministers controlling the Commissions's programme, "it is quite clear there will be a linkage between certain Eureka projects and the Commission's programme". According to Research Commissioner Karl-Heinz Naries. the programmes can be complementary because the Commission's programmes are pre-competitive and Eureka's clearly competitive.

'A senior commission official at the meeting said there could still be "considerable differences" in arranging cooperation between Eureka and Commission programmes, however. For example, the two large environmental projects (EURO-MAR on sea pollution and EUROTRAC on tracing air pollution) included in Eureka on West Germany's insistence overlap strongly with Commission research and are not aimed at winning markets.

Robert Walgate

Laboratory safety

Just how hot is Harvard?

Boston, Massachusetts

HAVE the mistakes in the management of radioactive materials, for which Harvard University last month received a \$2,500 fine from the Nuclear Regulatory Commission (NRC) been corrected? Harvard vice-president Robert Scott says they have. But graduate students in the medical research area have a different tale to tell. Left unresolved, according to the students, all of whom were unwilling to be named, is the pervasive mishandling of radioactive materials stemming from short cuts taken because of research pressure and inadequate training.

"Safety regulations are often perceived as a waste of time, standing in the way of a Nobel prize", said one student. The risks of this approach are high — a laboratory stripped of its NRC licence loses its research edge as well as its personnel - yet a fear of a loss of prestige could cause management to look the other way. Dr Warren Wacker, director of Harvard's University Health Services, denies such blinkering at Harvard. Using radioactivity is a privilege, he said, and he would brook "no nonsense and no pressure" in its management. As proof, he pointed to the three well-known laboratories in microbiology and AIDS (acquired immune deficiency syndrome) research that have just lost their licences for such infractions as inadequate cleaning of a spill.

NRC fined Harvard, according to an

spection and enforcement, less because of the twelve specific incidents cited than for "lack of effective management control and oversight" of radioactivity. As a result, the violations that occurred were of particular concern to NRC because "they could have resulted in unnecessary radiation exposure to individuals".

By law, NRC can fine nuclear power plants up to \$100,000 per infraction per day, but academic institutions only \$5,000. On a severity scale of 1-5. Harvard's infractions were rated as 3, for which the highest fine is \$2,500. Harvard has been warned about a number of other incidents, but they were not deemed serious enough to warrant a fine.

NRC, savs Wacker, is cracking down on universities and Harvard, which is paying its fine without appeal, is not resisting. The salaries of two additional radiation health safety engineers will come from grants, not overhead. Other elements in Wacker's "model" programme will be continued — including surprise visits by Harvard's radiation service and immediate cancellations of licences for any serious infractions.

Radioactive materials are used on a daily basis in many medical research departments, amounting to "a couple of millicuries a week". Still, claims Wacker, "the highest level of radioactivity at Harvard is probably in the geology department in uranium ores, which are perfectly **Elizabeth Collins** French science

Legal niceties end an era

French scientists were on the streets of Paris last week demonstrating against what placards described at the "strangling" of public research by a government that has cut ten per cent from its 1986 research budget, hitting research harder than any other field of government spending. After five heady years of strong support for science in France, laboratory staff and university lecturers are shocked, and were issuing posters last week claiming that French research was "in a coma".

One of the latest and most extraordinary blows, however, is not of the government's making. The Conseil d'État, effectively the French supreme court, has ruled that a body which for three years had made all the appointments and promotions in France's premier research council, the Centre National de la Recherche Scientifique (CNRS), was illegally elected.

This extraordinary decision, made on the basis of a legal technicality, to disestablish and annul the "Comité National" of CNRS, in theory invalidates all decisions taken by that body since 1983, thus affecting many of the academic scientists and technicians in France. In practice, the decision may play into the government's hands, as its science advisers have long felt that the Comité National is too dominated by trades union interests. Paradoxically, it was a union that first made the legal complaint to the Conseil d'État back in 1983, over an election which had been designed to reduce union power.

Now, the ministry of research and the council of ministers will have the freedom to define a completely new election procedure at just the moment they would have desired — after a change of government from the political left to the right.

Appointments and promotions made by the Comité National since 1983 are thought likely to stand. But young researchers who recently attended interview boards arranged by the Comité and have been offered places in CNRS are less lucky. Some 375 of the 500 affected will be offered one-year temporary posts instead—to be reviewed next year when a new Comité is in place—and the others will fall by the wayside. This represents a 25 per cent reduction in the scientific recruitment rate projected by the previous government.

Italian biotechnology

New initiative is called for

Rome

ITALY needs to spend a million million lire (£420 million) on a massive biotechnology programme over the next five years, according to a new report from the Italian National Committee for Biotechnologies. That, says Minister of Research Luigi Granelli, will give the government a tool to make Italy competitive in previously neglected sectors such as chemicals and agriculture.

Four areas are earmarked for funds: fundamental research in public centres and universities including three special projects from the Consiglio Nazionale della Ricerca (CNR), the national research council (25 per cent of funds), national research involving both scientific bodies and industry (40 per cent), the finance of research societies and stimulation of industrial activity (25 per cent) and training of researchers (10 per cent).

Established in July 1985 by Granelli, the committee includes 14 representatives from universities and public research centres and eight from industry. Coordinated by Professor Arturo Falaschi, director of the CNR Institute of Genetic Engineering in Pavia, the report looks largely at the short term. In countries such as the United States and Japan, says the report, basic research in biotechnology is

strongly supported by government, with private investment strong in biomedicine in the United States and in agriculture in Japan. In Europe, adds the report, the United Kingdom leads in biotechnology, but good state-financed programmes have been launched elsewhere.

Italy has good scientists, says Professor Luigi Rossi Bernardi, CNR president, as well as a good research tradition at the Institute of Molecular Biology. And there is the new International Centre for Genetic Engineering and Biotechnology in Trieste (see p.3). But this is not enough for Italy to catch up with other nations.

The biomedical field, says the report, is likely to yield returns in the short term, while agriculture, the food industry and fine chemicals have good medium-term prospects. So the report suggests doubling in five years the number of researchers in biotechnology in public centres such as CNR and ENEA (the national centre for alternative energy), as well as in the universities and health ministry, rather than in industry.

To coordinate the programme, it is suggested that either the present committee should be institutionalized or a National Institute of Biotechnology should be set up like that for nuclear physics.

Paola di Paoli

US space

Air Force moves on launchers

Washington

The US Air Force has announced plans to build at least twelve medium launch vehicles (MLVs) as an alternative to the space shuttle for launching military payloads. In seeking the new rocket, the Air Force has indicated it wants potential suppliers to develop a commercial version of the rocket to compete with Europe's Ariane for commercial payloads.

The new rocket will be able to launch 10,000-lb payloads into low Earth orbit, and 2,200-lb payloads into a 10,000-mile high circular orbit. The Air Force intends to use the new rocket primarily to launch its Navstar satellites, part of a new Global Positioning System under development.

Air Force interest in a complementary commercial vehicle may seem odd, but building a launch vehicle with commercial applications would have the obvious benefit of spreading development costs. Air Force Secretary Edward C. Aldridge has consistently shown concern for the viability of the US space programme, according to space policy consultant Christopher Roberts, and by providing a steady customer, the Air Force can go a long way towards assuring the success of a commercial launcher. John Pike of the Federation of American Scientists takes a more cynical view, believing that the new MLV results from an "unholy alliance" between the Air Force and the rocket manufacturers. As Pike sees it, the Air Force gains more positions for uniformed officers in its space command, and the manufacturers get to crank up their production lines.

Money for starting the procurement process of the new MLVs was in the urgent supplement appropriations bill passed by Congress last week. Also in the appropriations bill were funds for an additional 13 Titan 34D7 rockets, the workhorse of the Titan series. With the new orders, Martin Marietta, the manufacturer of the Titan 34D7, will be in a position to compete with Ariane-4, due to launch next year, should the company decide to enter the commercial launch arena.

In a related development, the National Aeronautics and Space Administration (NASA) announced last week that it was offering Indonesia the opportunity to launch its Palapa communications satellite aboard a Delta rocket. The Palapa satellite had been scheduled to fly on the shuttle last month. If Indonesia accepts, NASA will have to build one more Delta to meet its launch commitments. But NASA denies that the new Delta would mark NASA return to expendable launch vehicles.

Joseph Palca

UK science

Save British Science takes off

An extra £100 million pounds a year is the minimum needed to "save British science" according to the new pressure group of the same name. The figure comes in the first major effort by Save British Science (SBS) to win influence in Parliament: the presentation of evidence to the House of Lords Select Committee on Science and Technology

The SBS campaign was born last January with a half-page advertisement in The Times newspaper protesting against the underfunding of UK scientific research. At that time, it was not a formal organization, but the response the advertisement provoked made it seem worthwhile to become so. More than 2,500 scientists have already contributed financially. From last week, SBS is a formally constituted body and will start to collect membership fees from individual scientists and students and from societies and companies. Its aims are to "communicate to the public, parliament and the government a proper appreciation of the economic and cultural benefits of scientists' research . . . ". A London office is being opened.

Individual members of SBS have argued their case with the recently departed Secretary of State for Education and Science, Sir Keith Joseph, and have urged scientists to write to their Members of Parliament, but the evidence to the House of Lords is their first major move.

The House of Lords select committee has just finished taking evidence on the state of British science - SBS actually squeezed in just after the deadline. The committee is expected to send a report to the Secretary of State or to call for a debate in the House of Lords on the state of science, perhaps in the next session.

SBS's evidence is not an overall analysis of British science but a collection of reallife stories from scientists depicting the difficulties they face. Taken as a whole, it should depress their lordships: libraries where core international journals can no longer be afforded, electron microscopes and other vital equipment without funds to keep them in use, talented postdoctoral students who vanish abroad, equipment that ceased to be up to date a decade ago, time wasted on an endless struggle to obtain funds, and out of work young researchers who carry on as "DHSS fellows" (living on social security payments).

A case is made that the damage extends to research with clear economic potential. Experts in high growth areas such as electronics are packing up and going abroad where they will help to train the next generation of foreign competitors. The fear is expressed that once Britain falls too far | (ERS-1) will carry altimetry instruments. | NASA projects.

behind, it will become impossible to catch up again and there will be nothing to offer in international exchange and collaboration. Evidence is given that Britain is already regarded as not being a serious partner in European ventures.

For Save British Science, the remedy lies in tackling the "alphas", grant proposals given the highest priority rating. In the past, these would have received automatic support. Now, around threequarters are funded to about two-thirds of the sum requested, but full amounts are rarely asked for as there is so little chance of success. Adequate support for all alpha-graded proposals plus the basic infrastructure needed for them would cost an extra £100 million a year.

That money would still, however, be

little more than a stopgap. What SBS wants is a coherent scientific policy that would raise the low level of investment in research by UK industry in comparison with other nations and establish a "new sharing of responsibilities between government, higher education and industry

The future success of SBS's own campaign must depend on its forming close links with industry. The only argument that is likely to carry real weight with the government is that basic research is essential if there is to be applied research that benefits British industry

So far, SBS's support has come almost entirely from academics, implying that the two constituencies of industrial and university researchers are far apart. In the future there will be efforts to recruit industrial support, beginning with companies that have links to universities and those dependent on high technology.

Alun Anderson

Ocean satellites

Topex launch comes closer

Washington

Congress has given the National Aeronautics and Space Administration (NASA) a green light to seek final design proposals for the Topex/Poseidon satellite. A joint project with the French space agency (CNES), Topex/Poseidon will provide the most accurate data on ocean surface topography ever recorded.

Topex/Poseidon is scheduled for launch in 1991 aboard the French rocket launcher Ariane. Three companies are in the running for the final contract to build the satellite: Fairchild Industries, RCA and Rockwell International have all completed design proposals, and will now provide a final design to NASA by the end of September. In addition to approving selection of the hardware, Congress is allowing NASA to solicit proposals from potential users of the satellite. According to the agreement with CNES, the French will review scientific proposals from most of Europe and Africa, while NASA will judge proposals from the rest of the world.

One of the primary beneficiaries of the ocean topography data will be the World Ocean Circulation Experiment (WOCE). Carefully calibrated altimetry data from Topex/Poseidon will provide an acccurate picture of ocean currents. Because Topex/ Poseidon has a design life of three years and will carry enough fuel to last two years longer - oceanographers expect to build up a picture of variations in ocean currents as well as their steady-state behaviour.

Both Japan and the European Space Agency (ESA) also have plans for complementary satellites. Japan's Marine Observations Satellite (MOS-1) and ESA's Earth Remote Sensing Satellite Having several satellites in orbit concurrently will provide useful cross checks on their data, says Worth Nowlin of Texas A&M University, co-chairman of the US WOCE scientific steering committee Nowlin also says the accuracy of Topex Poseidon data will help to validate less precise measures from the other satellites Another advantage of Topex/Poseidon will be its orbit. At 63.1 degrees inclination and 1,334-km altitude, Topex Poseidon will pass over the same point on Earth once every ten days. Using a laser tracking system, NASA and CNI-S will be able to calibrate the satellite's altimeters regularly. In addition, because it will not be launched into a Sun-synchronous orbit. Topex/Poseidon will provide data on solar tides that typically confound ocean current measurements.

Topex/Poseidon fits nicely into the scheme of coordinated Earth observations foreseen by the Earth System Sciences Committee in its report to NASA released last week (see Nature 321, 801: 1986). The committee has endorsed the Geopotential Research Mission (GRM) as a sequel to Topex/Poseidon, GRM will provide detailed measurements of the Earth's gravitational field, giving an absolute reference point for sea-surface heights measured by Topex/Poseidon.

Money for the final design stage of Topex/Poseidon has already been allocated to NASA, but Congress must still approve funds for full-scale development Until the Reagan administration says how it plans to balance manned and unmanned missions in the wake of the Challenger accident. Congress is likely to postpone definite decisions about support for Joseph Palca

CORRESPONDENCE-

Darwin, Lyell and gradualism

Sir-In an elegant essay, Rhodes' convincingly demonstrated that Darwin was not a strict gradualist — that he was, in fact, a pluralist and his views overlapped what over the past decade or so has been hailed as a new theory, "punctuated equilibria". According to Rhodes, Darwin recognized a component of stasis, a tenet of punctuated equilibria, and repudiated the gradualistic aspect of evenness in transformation but "...whether it was 'slow' depends on our definition of speed"; slowness is not synonymous with gradualism. Darwin, Rhodes correctly points out, clearly appreciated the significance of local, periodic speciation and its representation in the fossil record. Although rapidity of speciation is associated with punctuation, Rhodes argues that this rapidity might well be encompassed within the "gradualism" of Darwin; whether "gradual" or "rapid" becomes a matter of definition.

Recently, Dawkins2, in his review of a book Time Frames: The Rethinking of Darwinian Evolution and the Theory of Punctuated Equilibria by one of the originators of the theory, Niles Eldredge, substantiates many of the claims of Rhodes. Although the fervent punctuationists have stressed the revolutionary and anti-darwinian aspects of the concept, Dawkins states that "it lies firmly within the neo-darwinian synthesis". Darwin emphasized the term "gradual" in his campaign against creationism; in such a context, explains Dawkins, gradualism is practically synonymous with evolution itself. "The punctuationists deluded themselves that they were saying something revolutionary. And it was all due to a simple verbal misunderstanding: a confusion of two senses of the word 'gradual'."

In a very recent defence of "lyellian uniformitarianism", I4 have, by referring to Lyell's original works, demonstrated that he certainly appreciated episodicity, both past and present, and clearly incorporated that concept in his use of 'gradual". In a parallel situation (and with some overlap) to Darwin's combat with creationists in the palaeontological and biological realm, Lyell was waging an intense philosophical battle against the catastrophists, a still very vociferous and influential group in the 1830s when his early editions were written. In comparison with this antagonistic philosophy, which emphasized truly cataclysmic events beyond our present knowledge, Lyell's uniformitarianism seemed gradualistic, and was - relatively speaking; he used "gradual" in a broader sense than most have realized. One quotation from the first edition of his Principles of Geology describing the episodic uplift of a faultbounded mountain range serves as a representative statement of his concept of "gradual": "We know that one earthquake may raise the coast of Chili for a hundred miles to the average height of about five feet. A repetition of two thousand shocks of equal violence might produce a mountain chain one hundred miles long and ten thousand feet high. Now, should only one of these convulsions happen in a century, it would be consistent with the order of events experienced by the Chilians from the earliest times5 "

In another recent review, Cloud6 criticized authors who labelled Lyell a gradualist, advising them to review original sources. Cloud has suggested (personal communication), correctly I feel, that Lyell's sense of gradual and uniform was with regard to the "long average". Although he frequently used the word uniformity, it seems clear from content that what he had in mind was far from simple gradualism.

I think that both Darwin and Lyell have been rather seriously misjudged with regard to their use of "gradual". For more than a century, it seems we have cast aspersions on their gradualism without appreciating the context of their times and, apparently, frequently without carefully consulting the original sources.

Problems of Africa

SIR-I have often wished that your Opinion and News columns showed more awareness of the Third World's worsening problems; but if your editorial "Who will pity Africa?" (Nature 321, 548; 1986) is the best you can do, it might be better to remain silent. In one column of pontification you reveal a remarkable ignorance of Africa's history and economy, and even of recent events in the continent.

You say that Uganda, once a kind of paradise, "has now settled for inter-tribal violence and the chaos that follows". Apart from the fact that Britain fostered tribal rivalries in colonial days by recognizing the Kabaka of Buganda as ruler, and then backed two disastrous leaders (Obote, Amin and Obote again) who deepened these divisions, you seem to have missed the news earlier this year that Uganda now has a widely popular president (Musevini) who offers real hope of reconciliation.

Your reference to Nigeria having "squandered" its oil wealth is also somewhat misplaced, in view of the fact that Britain's oil boom appears to have financed nothing more tangible than tax cuts for the better-off. Would you call this a good example?

Worse than all of this, however, is your failure to comment on the external factors, particularly falling commodity prices, that lie at the heart of Africa's crisis. For example, Tanzania spends 60 per cent of its external earnings on oil, and while 1 tonne of tea paid for 60 barrels of oil in 1972, by 1980 it bought only $4\frac{1}{2}$ barrels. In the same period, the amount of coffee needed to pay for a lorry rose from 5 to 28 tonnes. This is the "free market" over which Africa has no control.

There has been no shortage of "good ideas" on what to do next, but Western governments have found most of them deeply unpalatable. Instead of joining Mr Schulz in lecturing Africans on their improvidence, you could start by asking why Britain and the United States have so far failed to contribute to the special programme for sub-Saharan Africa set up by the International Fund for Agricultural Development.

MICHAEL SPENCER

34 Bayham Road, Sevenoaks, Kent TN13 3XE, UK

Condoms in Japan

SIR-Legalization of the contraceptive pill seems to be regarded as an entirely positive development1. The cautiousness of the Japanese authorities has, however, contributed greatly to the wide popularity of the condom, which is more frequently used than any other form of contraception.

The low incidence of acquired immune deficiency syndrome (AIDS) in Japan and the relaxed attitude towards the possible spread of the disease among the general population, as well as the low incidence of infertility caused by salpingitis', may be explained in part by the widespread use of the condom.

Rather than Japan copying Western habits of contraception, it would be better for those in the West to attempt to understand (and possibly copy) the cultural patterns that make this simple contraceptive acceptable to Japanese men and women rather than being considered unnatural and unwelcome.

The proper study of mankind

Molecular biology has made the human genome accessible to laboratory investigation. But does that mean that the sequence of the human genome would be worth the effort?

There is no scientific reason for studying man. Thus one of the 120 speakers at this year's Cold Spring Harbor Symposium on the molecular biology of *Homo sapiens* from 28 May to 4 June. The issue arises because, as the programme was designed to demonstrate, there are now few fundamental questions in biology that cannot be explored using human genes and human cells.

This in itself is scarcely sufficient reason for overlooking the rather obvious shortcomings of man as an object of investigation. But there is one reason, just the same: the human species alone preserves its rare defective variants. Mouse mothers, whose matings are manipulable and whose generation times are manageable, tend to eat offspring that seem not quite right before they have grown large enough to be investigated, and thus destroy the rich mine of information that medical genetics has made available in man.

If we accept that man's sole unique contribution is his genetic diseases, the content of the Cold Spring Harbor Symposium has some interesting reflections to offer in the light of the debate, discussed in *Nature* (321, 371; 1986) and formally tabled at the symposium, on whether to launch into the gargantuan exercise of sequencing the entire human genome.

There have been two outstanding contributions of medical genetics to science. One is the analysis of mutant haemoglobins; the other is the remarkable achievement of Michael Brown and Joseph Goldstein (University of Texas, Dallas) who uncovered the cellular and molecular basis of the hypercholesterolaemia that predisposes to heart disease (see *Nature* 317, 569; 1985), the essence of which was reviewed by Goldstein at Cold Spring Harbor.

Cholesterol is cleared from the blood-stream in the form of a lipid – protein complex (LDL) that binds to a specific receptor (the LDL receptor) on the surface of cells, whence it is internalized by endocytosis and released to provide the substrate for the synthesis of cell membranes and steroid hormones, as appropriate. If the receptor-mediated internalization fails for any reason, the cholesterol builds up in the bloodstream, atherosclerotic plaques develop and heart disease ensues. By investigation of precisely why internalization does fail in individuals with familial hypercholesterolaemia, Brown

and Goldstein have built up a picture of the cellular and, more recently, the molecular biology of receptor-mediated endocytosis which has provided fundamental insights into these processes as well as clarifying the mechanism of atherosclerosis.

This has been possible only because Brown and Goldstein worked up to the molecular biology from classical genetics via biochemistry. More characteristic of latter-day triumphs were the papers presented by Louis Kunkel (Boston Children's Hospital) and Stuart Orkin (Harvard Medical School), both published in this issue of *Nature* (pp 73 and 32). They have arrived directly at the genes responsible for two human genetic diseases without engaging with the intervening biochemistry.

Kunkel and his collaborators have succeeded in forging a path to the gene for Duchenne muscular dystrophy (DMD); Orkin and his colleagues have identified, cloned and sequenced the gene for X-linked chronic granulomatous disease (CGD). Neither group is any the wiser about the molecular or cellular mechanisms of the disease.

From this point of view, DMD and CGD present problems of a different order. DMD is a programmed wasting disease of muscle whose mechanism and site of action are wholly unknown, whereas CGD is an immune deficiency known to be consequent upon a defect in the oxidase system in phagocytic cells. Peter Goodfellow explains in an article on p. 12 the route by which Kunkel and his collaborators have arrived at a region of 20,000 base pairs comprising possibly no more than a part of the DMD gene, and what this implies for the daunting prospect of identifying the gene product or products. The problem here, and much of the excitement, is that there is so little idea what to look for.

The CGD gene is much more tractable. Starting with genetic linkage analysis using polymorphic DNA probes, Orkin and co-workers identified a sequence that is transcribed specifically in normal phagocyte but not in the phagocytic cells of three of their four CGD patients. The fourth patient produced a transcript containing a small deletion that presumably abrogates the production of a functional protein. Whether the transcript encodes one of a number of known but poorly characterized components of the oxidase system, or some so far unknown enzyme,

may require some ingenuity, as well as some biochemistry, to discover.

The substantial challenge now facing Orkin and Kunkel and their collaborators is in no sense a reflection on the quality of the work or the validity of their approach. But it is an inevitable consequence of approaching the DNA directly, and thus has a direct bearing on the desirability of sequencing the rest of the human genome

In the discussion on that topic at the symposium, Paul Berg (Stanford) set out the issues—is it feasible, who will pay and is it worth it? Walter Gilbert (Harvard) seraphically chalked up the tally—three thousand million bases at 10° bases per year equals 30,000 person-years or, at the current rate of $2 \times 10^{\circ}$ bases per year, but allowing for the 6 million already sequenced, 1,000-1,500 years to finish all of it; at a going rate of \$1.00 a base

Nobody seems to doubt that it is feasible; nor that with improvements in technology it can be done in perhaps a century or less. The question is whether it is worthwhile. There is a general conviction that, even with funding from the US Department of Energy (see *Nature* 321, 371; 1986), the project would be bound to divert resources from other areas of research. In return, it is argued, it will encourage innovative technology and provide an information resource that would nourish other areas.

But technical innovations are already occurring with impressive momentum: and as an information resource, the sequence of the human genome is an extremely doubtful asset. If the skill and ingenuity of modern biology are already stretched to interpret sequences of known importance, such as those of the DMD and CGD genes, what possible use could be made of more sequences? Moreover, it is believed that roughly half the human genome is nonsense and repetition; and those who argue that there may be meaning in the nonsense and function in the repeats are not likely to prove their point by sequencing it all.

The difficulty is the same for all attempts to answer biological problems by reading DNA: unless you have a very good idea how to phrase the question, the sequence is not going to give you the answer. Blind sequencing at the expense of good ideas would, in the words of David Botstein, be for biologists to "indenture [themselves] to mindlessness".

Miranda Robertson

Duchenne muscular dystrophy

Collaboration and progress

from Peter N. Goodfellow

PROGRESS in science often reflects the Hegelian dialectic between collaboration and competition. Collaboration allows the most efficient use of resources and competition can generate original approaches to solving problems. Geneticists, molecular biologists and clinicians studying Duchenne muscular dystrophy (DMD) have demonstrated both originality and a willingness to collaborate. The scale of that collaboration can be estimated from the 75 co-signatories to the paper' on page 73 of this issue.

DMD, a devastating X-linked genetic disease afflicting one in every 4,000 newborn boys, is characterized by progressive muscle wasting that is fatal during the second or third decade of life. The apparently simple X-linked mode of inheritance makes DMD a model system for the application of the techniques of molecular genetics. For any genetic disease of unknown actiology the strategy is the same (see ref. 2): pinpoint the location of the defective gene; starting from neighbouring reference points 'walk' to the gene by isolating overlapping DNA sequences; and deduce the nature of the disease from. the sequence of the gene and the gene alterations found in disease sufferers. For DMD the gene has been localized and chromosomal walks have begun. Unfortunately, nature has a habit of putting new twists into the theoretical constructs of scientists. New results reviewed at the recent Cold Spring Harbor Symposium (see page 11) and described by L. Kunkel and collaborators' suggest that DMD gene identification and description will prove difficult: either the gene is very large or the region is very complex.

Three different paths have led to the chromosomal position of the DMD gene. The first followed from the discovery of rare female DMD patients resulting from chromosomal translocations between one X chromosome and an autosome. In each case the breakpoint on the autosome varies but the breakpoint on the X chromosome is similar^{3,4}. In normal females one of the two X chromosomes is inactivated to avoid gene-dosage problems. What happens in the DMD females is that the normal X chromosome is inactivated, and DMD results because the breakpoint on the translocated X chromosome disrupts the DMD gene. The second path follows from classical mendelian genetics and involves the identification of sequences genetically linked to the DMD gene'. The third path followed from the discovery of a boy with DMD who had a deletion of DNA from within the short

arm of the X chromosomes⁶. None of the paths was well signposted and there was potential for straying. But the fact that all three paths led to the same point within Xp21 on the short arm of the X chromosome provided overwhelming evidence that this was the chromosomal position of the *DMD* gene⁷.

The next step was to isolate the DNA sequences within the region Xp21 that correspond to the disease gene. Unfortunately, this region contains about 10⁷ base pairs (bp) of DNA and the closest DNA sequences used as genetic markers were at least 10 per cent recombination away from the DMD gene. If it is assumed that 1 per cent recombination corresponds to about 106 bp, walking the 107 bp to the disease locus would be a daunting task. In the near future, the new technologies of chromosome jumping and hopping may ameliorate the worst aspects of chromosome walking (see the recent News and Views article2 by Peter Little). But the groups of L. Kunkel (Boston) and R. Worton (Toronto) decided not to wait for the future.

The short-cut taken by Kunkel and colleagues was to develop and exploit an accelerated hybridization technique which enabled them to clone, by subtraction, sequences defined by chromosomal deletions^{8,9}. That taken by Worton and colleagues was to clone the sequences at the breakpoint present on the X chromosome of a female DMD patient¹⁰. One of

the sequences described by Kunkel and collaborators is deleted from between 5 and 10 per cent of all DMD patients. In several other human genes about 10 per cent of mutations causing disease are caused by small deletions within the gene (for example, HPRT; ref.11). By analogy with these genes it was thought that the sequence DXS164 was derived from within the DMD gene. It was therefore very disappointing to learn that 5 per cent recombination occurs between DXS164 and the DMD gene; that is, if DXS164 is part of the disease gene it would not be expected to recombine with the disease phenotype at a detectable frequency. Another disappointment was the discovery that the sequence XJ-1.1 isolated by Worton et al. from the X-chromosome translocation breakpoint also recombines with the DMD gene at about 5 per cent despite the fact that some patients had deletions which included both XJ-1.1 and DXS164. Perhaps these observations were not totally unexpected — careful cytogenetic observation had suggested that not all the X-chromosome breakpoints associated with DMD were precisely in the same position4 and chromosomal translocations may cause deleterious effects over large areas.

In an attempt to regain the path leading directly to the DMD defect, Kunkel et al. describe in this issue the cloning of 140,000 bp of DNA around the DXS164 locus and the use of the isolated sequences to analyse DNA from 57 DMD patients with deletions. As the authors point out, ascertainment of the deletions may be biased because more patients have been screened with the original DXS164 probes than have been screened with probes from

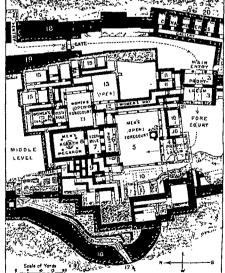

100 years ago

The recent discoveries at Tiryns

THE excavations, made during the last two years at Tiryns, by Dr. Schliemann and Dr. Dörpfeld, have thrown new light on what has been hitherto an almost unknown period of Greek history when Hellenic civilisation had not yet emerged from its Oriental cradle, nor developed its highly cultured systems of social and political government.

The literature of Greece has made us familiar with the later times, when the individual was for the most part merged in the State, and when the wealth and artistic skill of each city was devoted to public uses, such as the Council-chamber, the Agora, or the stately temples of the gods, rather than to the luxury of any one person.

But at Tiryns a very different picture is presented to us: we see a single autocratic chieftain, ruling in a sort of feudal state, and occupying a magnificent palace, surrounded by the humbler dwellings of his circle of retainers; while, instead of the utmost resources of the architect, the sculptor, and the painter being lavished on the shrine of the presiding diety, a mere open-air altar is dedicated to the

PLIN OF THE PALACE MEASURED BY DR. DÖRFFELD.
god, and it is the chieftain's house which is
decked out with the splendours of gilt bronze,
marble sculpture, and painted walls.
From Nature 34, 218; 8 July, 1886.

other parts of Xp21. Most of the deletions have removed the whole 140,000 bp of the expanded DXS164 region. One deletion of 40,000 bp is completely contained within the DXS164 region and most of the other deletions overlap each other in the DXS164 region. However, five deletions within DXS164 show no region of overlap. The breakpoints in the latter deletions may be separated by up to 80,000 bp of DNA. The only obvious conclusion is that the deletions are large, a conclusion supported by the deletion of the flanking markers and, occasionally, adjacent disease loci. These deletions are quite unlike the small deletions associated with mutations at other disease genes, although a similar spectrum of large deletions on the Y chromosome has been associated with the generation of XY females12.

Conclusions about the nature of the DMD gene must remain speculative and are based on two plausible, but unproven, assumptions. The first is that the deletions are simple and not part of complex rearrangements, which can be tested. The second assumption is that the deletions, when present, are responsible for the disease and are not merely markers for the disease. Accepting these limitations, the simplest interpretation is that either the DMD gene is large or mutation in several different genes in the same region can cause the disease. The deletion data are consistent with a single large gene of 100,000-200,000 bp — no larger than the factor 8C gene¹³. Less consistent with this view is the apparent variable position of the *DMD* locus as defined by the recombination and deletion studies with respect to the DXS164 locus. To accommodate these results either one or several genes need to be spread over a distance as large as several million base pairs. Alternatively, recombination rates in this region may be greatly elevated. Neither possibility is without precedent: the bithorax gene of Drosophila is greater than 100,000 bp, the same fraction of the human gene would represent 2,000,000 bp; and in human male meiosis the pseudoautosomal region shows a 10-fold elevation in recombination.

A more radical explanation of the results acknowledges the variable order of DMD with respect to DXS164. If a polymorphism exists in the human population for inversion of a few million base pairs in the Xp21 region, several of the observed phenomena could be explained. Regions of inversion would lead to different gene orders in different families. Recombination outside the inversion followed by a second abnormal and rare (10⁻³) recombination event within the inversion (perhaps between ubiquitous and inverted repeat sequences) would result in the generation of large deletions. This model predicts the concomitant generation of duplications and the observed high frequency of mutation at the DMD locus. A disadvantage 1 of the model is that it requires the new assumption of an inversion present in the population at high frequency. Molecular analysis of deletions of the gene encoding the LDL receptor demonstrates repeat sequences flanking the breakpoints within the gene (D. Russel, Dallas). However, Kunkel et al. have not seen a similar preponderance of repeats associated with breakpoints in DMD.

Several groups are attempting to resolve these questions by constructing restriction maps of the Xp21 region of the X chromosome using pulse-field gradient gel electrophoresis (K. Davies, Oxford; P. Pearson, Leiden; see ref. 2). But even more pressing is the need to find transcribed sequences within the DXS164 region. Several strategies are possible, but the most straightforward is to screen messenger RNA isolated from adult muscle with probes derived from the expanded DXS164 region. Another approach is to screen for conserved sequences between man and mouse. Using this method Kunkel et al. find potential exons within the DXS164 locus which are also X-linked in the mouse and Worton and collaborators find conserved exons near XJ-1.1 []

Geomagnetic reversals

Evidence for asymmetry and fluctuation

from Jeremy Bloxham

FIELD reversals, occurring roughly every million years, are the most dramatic of the wide range of phenomena exhibited by Earth's magnetic field. And the next reversal on Earth may not be so far away: if the current rate of decay of Earth's dipole component is maintained it will vanish in less than 2,000 years' time. Reversals are studied using palaeomagnetic techniques to recover the remanent magnetization of lavas and sediments; in recent years, attention has focused on obtaining reliable records spanning actual reversals, in order to build up a description of the field in transition. Two papers in this issue^{1,2} present such records obtained from sedi-

Most previous work has concentrated on using lavas to study the field in transition. From these studies a picture, albeit rather blurred, has begun to emerge as to how the field reverses, and it has been possible to draw some tentative conclusions about the working of the dynamo during a reversal.

First came the recognition that the reversing field is non-dipolar³. The more interesting issue of whether the field is axisymmetric is still undecided: the evidence tends to suggest that reversals are initially axisymmetric, but may become nonaxisymmetric as the reversal progresses. Hide suggested that reversals are initiated if the field becomes axisymmetric, since axisymmetric fields cannot be maintained by dynamo action and must decay diffusively. However, it appears that reversals are not entirely diffusive; instead. fluid motions in the core actively contribute to the reversal process. This viewpoint is supported by the observation of Prévot et al. of very rapid variations in the field during reversals, variations with characteristic times very much shorter than appropriate diffusive timescales. Other work has indicated that reversals take place in two distinct phases'; in the first phase an intermediate state is reached from which either the reversal is completed, or the field returns to its original polarity.

On page 27 of this issue Valet et al. report results obtained from marine clavs from western Crete. They find evidence of short-term variations in the field, the amplitude of which seem to increase during the reversal. They also find evidence of an intermediate state. Now that studies based on both lavas and sediments have indicated some of the same characteristics of reversals, the evidence that such characteristics are real is greatly strengthened. In a forthcoming issue, Herrero-Bervera and Theyer² will report on four transition records obtained from deep-sea sediments from the north central Pacific Ocean. They find evidence that the transition field is non-axisymmetric and that it is characterized by quite rapid fluctuations. They also consider which of the two common phenomenological models of the reversal process is favoured by their data. The

flooding model, whereby the reversal is believed to be initiated in some region of the core and subsequently spreads, or floods, throughout the core, seems to be favoured over the standing model, whereby the dipole reverses while most of the non-dipole field is unaffected.

Valet et al.'s results also indicate the presence of longer-term variations, of between 2,000 and 4,500 years periodicity. Sediments are a very good way of detecting such long-term variations, although it is hard to pinpoint their precise period because of uncertainties in the sedimentation rate. Interestingly, these variations appear to be unaffected by the reversal. They claim that this observation has some relevance for the validity of the frozenflux approximation.

The frozen-flux approximation which has recently become the object of renewed controversy - consists of neglecting the effects of magnetic diffusion in the core so that the secular variation is considered as being due entirely to the advection of magnetic field lines by the fluid motions in the core. The application of the frozen-flux approximation to reversals — a process with rather longer timescale than is normally believed appropriate for the approximation — was first considered by Gubbins and Roberts8, who presented simple examples of frozen-flux reversals, and showed that axisymmetric, frozen-flux reversals are impossible. Valet et al. refer to the recent extension to the frozen-flux theory of the secular variation made by LeMouël", who showed that the force balance at the top of the core is likely to be geotrophic. This imposes strong constraints on the flow at the core-mantle boundary and, in particular crossequatorial flow is not permitted, a condition which makes geostrophic frozen-flux reversals very hard, if not impossible, to

LeMouël also showed that with geostrophy and frozen-flux the dipole component of the field has no effect on the secular variation: Valet et al.'s observation that certain aspects of the secular variation, namely the long-term variations, are preserved through a reversal tends to support LeMouël's results. Moreover, they claim that this suggests that only the internal parts of the core are involved in the mechanism of a reversal. Herein lies a problem: for not only are geostrophic frozen-flux reversals very hard to effect, but if the reversal process is effectively frozen-flux then the uppermost part of the core must be involved in the process otherwise the reversed field originating deeper in the core would never be able to permeate the perfectly conducting fluid overlying it.

Alternative explanations of the persistence of these long-term variations are available. A wide variety of types of oscillatory behaviour are possible in the

core, from relatively simple hydrodynamic waves to fully nonlinear dynamo oscillations. Hide considered free hydrodynamic oscillations, the period of which depend on the Earth's rotation rate and the strength of the toroidal field in the core. Of these the former is certainly constant to a very good approximation through a reversal and the latter may not necessarily change greatly. The period of Hide's fundamental mode of oscillation, with the assumption of a toroidal field strength of 100 µT, is 2,900 years.

The study of reversals seems to be typical of other branches of geophysics: as the available observations have improved, so the complexity of the process has become apparent. However, the two papers in this issue do reinforce the picture of fluiddriven reversals, characterized by a Cambridge, Massachusetts 02138, USA.

metastable intermediate field configuration, that has been emerging over the last few years. Perhaps now the ball is back in the court of the dynamo theorists to explain the observations, but given the highly nonlinear nature of the dynamo problem, such a prospect seems rather dim.

Cancer

Cell growth control mechanisms

from Tony Hunter

Understanding the cellular basis of cancer means being able to describe the biochemistry of the regulated pathways between cell surface and nucleus that control cell growth. Two concurrent recent symposia* on the activation and inhibition of oncogenic proliferation provided much new information on the balance of regulatory influences that constrain the growth of normal cells and fail in cancer.

On the basis of a simple observation made some 15 years ago, Henry Harris inferred the existence of 'tumour suppressor genes': if cells from two highly malignant tumour lines are hybridized, the resultant hybrid is usually non-malignant. This implies that many oncogenic mutations involve the loss of function (that is, that they are recessive). More recently, evidence for such recessive mutations in human tumours has emerged from studies of hereditary predisposition to cancers such as retinoblastoma and Wilms' tumour, which are characterized by the loss of a specific region of both copies of chromosome 13 or 11, respectively. These observations imply that the missing region contains a suppressor gene, and have no doubt helped to stimulate the recent resurgence of interest in suppressor genes, which three groups have been reinvestigating at the molecular level.

E.J. Stanbridge (University of California, Irvine), for example, reported on the occasional tumorigenic segregants that arise from hybrids between normal human fibroblasts and tumorigenic HeLa cells, which are generally non-tumorigenic. A common feature of these segregants is the

*Growth Factors, Tumour Promoters and Cancer Genes and Interferons as Cell Growth Inhibitors. UCLA Symposia held at Steamboat Springs. Colorado, 6-13 April 1986.

loss of a single copy of chromosome 11 or 14, and, by using restriction fragment length polymorphisms, Stanbridge has been able to establish that in 5 out of 6 cases the normal fibroblast chromosome 11 has been lost. The introduction of a normal human chromosome 11 (marked with a drug-resistance gene) by mini-cell fusion into HeLa cells suppressed their tumorigenicity, implying the presence of a suppressor gene on chromosome 11. Hybrids of human keratinocytes with HeLa cells, which are of epithelial origin, are also non-tumorigenic, but in this case the tumorigenic segregants have lost chromosome 1 or 4. This suggests that cells of different embryonic lineages express different suppressor genes.

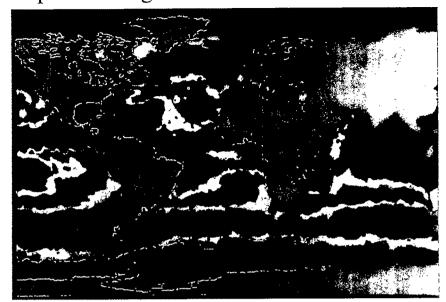

How do suppressor genes work? Experiments with transfected cells show that they can act to nullify the effects of exogenously added oncogenes. J.C. Barrett (National Institute of Environmental Health Science, Research Triangle Park), for example, has isolated tumorigenic Syrian hamster embryo (SHE) cells following co-transfection with the v-Ha-ras and v-myc genes and finds that such tumour cells nonrandomly lose one copy of chromosome 15. Fusion of these cells with normal SHE cells suppresses the tumorigenic phenotype, but the level of p21" is not decreased. (The occasional retransformant generated from such hybrids had again lost chromosome 15.) Similarly, normal hamster fibroblasts (CHEF) can suppress the phenotype of CHEF cells transformed with the EJ-Ha-ras oncogene on fusion, while expression of p21^m remains undiminished (R. Sager, Dana-Farber Cancer Institute, Boston). The transformed cells characteristically lack

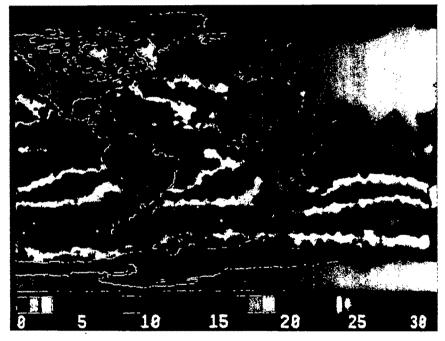

part of chromosome 3, which would be restored in the hybrids. This suggests that there is a suppressor gene on hamster chromosome 3.

One obvious area of interest is the identification of natural inhibitors of growth. It now seems that both interferon and transforming growth factor (TGF- β) may fulfil this function. Moreover, it is becoming clear that many growth factors induce the expression of a β -type interferon, presumably providing an inhibitory feedback loop to prevent runaway proliferation. Tumour necrosis factor (TNF), which paradoxically is cytotoxic to many human tumour cells while being a growth factor for normal human fibroblasts, induces interferon- β_2 (IFN- β_2) Vilcek, New York University Medical Center). Anti-IFN- β antibodies increase the growth-stimulatory effect of TNF, implying that the IFN- β_2 acts as a growth inhibitor. Platelet-derived growth factor induces delayed IFN-β, expression in quiescent mouse 3T3 cells (C.J. Stiles, Dana-Farber Cancer Institute). TGF-β, which like TNF has a dual stimulatory/ inhibitory nature depending on the target cell, induces IFN- β in fibroblasts for which $TGF-\beta$ is mitogenic, but not in epithelial cells for which it is a growth inhibitor (H.L. Moses, Vanderbilt University). Perhaps significantly, the induced IFN- β , is not an interferon which is classically involved in the antiviral response, but one with a rather poor antiviral activity, possibly because its natural function is in growth control. Haematopoietic cells stimulated with mitogens also conform to this pattern. For instance IFN-y is induced in T cells by the experimental mitogen phytohaemagglutinin (PHA) and in macrophages by the natural mitogen CSF-1.

A major signpost to pathways of tumorigenesis is provided by the evidence that one class of oncogenes is derived from the genes encoding the receptors for growth factors with protein-tyrosine kinase activities. In this connection, the most exciting result was the report of the activating mutation in the neu oncogene (C.I. Bargmann, Massachusetts Institute of Technology). The product of the neu oncogene, which is present in a series of ethylnitrosourea (ENU)-induced rat neuroblastomas, is a protein-tyrosine kinase, closely related to the epidermal growth factor (EGF) receptor, that is presumed to be a growth factor receptor, although no ligand has yet been identified. The activating event is a point mutation converting a valine to a glutamic acid in the transmembrane domain. Strikingly, the same mutation in the neu gene occurs in four independent tumour lines. As with other oncogene products of this type, it is assumed that the activated neu protein has constitutive, rather than ligand-regulated, protein kinase activity, although this re-

Tropical changes at the sea surface

Satellite measured sea surface temperatures (°C) show that on 28th June 1983 (bottom) the eastern tropical Pacific was unusually warm (during El Niño) while the eastern tropical Atlantic was cold. A year later (top) the sea surface temperature patterns in the two regions were reversed. Papers describing and interpreting the unusual conditions in the tropical Atlantic over this period will appear in *Nature* on 17th July. (Photograph from R. Legeckis, National Earth Satellite Service and O. Brown, University of Miami).

mains to be proven. If so, this clearly suggests that the transmembrane domain is much more important in transmembrane signalling by growth factor receptors than heretofore ceded.

How exactly the activation of proteintyrosine kinases contributes to tumorigenesis has not been established. There is, however, some evidence linking their activities to the phosphatidylinositol (PI) cycle system that is known to be activated by mitogenic signals. These signals are believed to stimulate a GTP-dependent phospholipase C in the cell membrane, leading in turn to the production of inositol trisphosphate and diacylglycerol, which activates protein kinase C. an effector on this mitogenic pathway.

It now seems there may be several ways for transforming proteins to accelerate PI turnover and the consequent activation of protein kinase C and Ca²⁻ release. C.J. Sherr (St Jude's Children's Hospital, Memphis), using a new *in vitro* assay for the membrane-associated phospholipase C, finds a GTP-dependent increase in activity in mink cells transformed by either *v-fes* or *v-fms*, both of which encode pro-

tein-tyrosine kinases. This implies that either the phospholipase itself or one of its regulatory factors may be phosphorylated and stimulated by the protein-tyrosine kinase in question. Cells transformed by v-ras, which does not encode a proteintyrosine kinase, also display increased phospholipase C activity, presumably by a different mechanism. By contrast, polyoma virus transformation may stimulate one of the PI kinases, possibly through direct phosphorylation by the activated form of pp60° found in association with the viral middle-T antigen (L.C. Cantley, Tufts University). This lipid kinase activity has been partially purified, which should allow the necessary biochemistry to be done.

The effector end of the cycle was addressed by two groups who reported the isolation of complementary DNA clones for protein kinase C using brain RNA as a source of messenger RNA. Evidence for a second closely related protein, which was differentially expressed, emerged from the cloning, suggesting that protein kinase C is a family of enzymes rather than a single-entity. This has obvious implications for understanding the regulation of protein kinase C by its natural regulators, Ca2+ and diacylglycerol, and by tumour promoters acting through the diacylglycerol binding site. The predicted structure of the enzyme is largely as anticipated, with the protein kinase domain near its carboxy-terminal end, but provides no clues to the nature and location of the Ca2+, phospholipid and tumour promoter/diacylglycerol binding sites. These will have to be defined by molecular manipulations of the cDNA clones.

To complete the circle, there is now evidence suggesting that some of the substrates of protein-tyrosine kinases are inhibitors of phospholipid turnover. Of two purified phospholipase A, inhibitors from human placenta (Barbara Wallner, Biogen Research Corporation), one seems to be identical to the known phospholipase A, inhibitor lipocortin, which in turn is probably the same as the EGF receptor protein-tyrosine kinase substrate p35 — at least to judge from a comparison of the lipocortin cDNA with the partial aminoterminal sequence of p35 (S. Cohen, Vanderbilt University). Moreover, the sequence of the second placental inhibitor (Wallner) reveals it to be the major retroviral protein-tyrosine kinase substrate p36 (my own work and R.L. Erikson, Harvard University); and there proves to be more than 50 per cent amino-acid sequence identity between lipocortin/p35 and p36, suggesting that there is a family of such proteins.

The ultimate target of most plasma membrane signalling systems is the nucleus. The *myc* and *fos* genes, which have been shown to be rapidly activated in quiescent fibroblasts by various mitogenic

stimuli, received the most attention. The mechanism of induction of the c-fos gene in PC12 cells (a pheochromocytoma cell line able to differentiate into cells with neuronal properties in response to nerve growth factor, NGF) has been studied in detail by T. Curran (Roche Institute of Molecular Biology) and E. Ziff (New York University Medical Center). There seem to be at least two induction pathways: first, NGF and fibroblast growth factor induce expression of the c-fos gene, possibly in part through the activation of protein kinase C; and second, opening of a voltage-dependent Ca2+ channel and an increase in intracellular Ca2+ may activate a calmodulin-dependent enzyme.

Except for their localization to the nucleus, there has been a paucity of clues as to the functions of the myc and fos proteins. The independent observations by R. Watt (Smith Kline and French Laboratories) and J.M. Bishop (University of California, San Francisco), which show that c-myc proteins co-localize with snRPs in the nucleus by immunofluorescence staining, is intriguing and suggests that the c-myc protein may have a role in RNA processing. The c-myc and c-myb proteins have previously been found to bind to DNA, albeit without displaying any sequence specificity. A fraction of the fos protein from induced PC12 cells will bind DNA (Curran), and the N-myc gene product (a phosphoprotein of relative molecular mass 65,000-68,000) can do the same thing (Bishop). Perhaps the DNA binding activity of all these proteins means that they can also interact with RNA and are involved in RNA processing.

Attempts to analyse the function of the

nuclear oncoproteins by genetic means has been frustrated by the apparent absence of these genes from genetically tractable organisms such as yeast and *Drosophila*. The characterization of a putative N-myc gene in *Drosophila* by M.E. Lambert (Cold Spring Harbor) may make it possible to carry out the critical experiments to test its function.

The work of A. Balmain (reported on page 78 of this issue) provides a nice example of how one can do molecular biology with the whole animal. Analysis of ras gene mutations occurring in papillomas and squamous cell carcinomas, induced by treatment of mouse skin with an ordered combination of an initiating carcinogen and a tumour promoter, shows that the different types of point mutation in the oncogenically activated c-Ha-ras genes detected by transfection correlate well with those known to be caused by the initiating carcinogen. In this model of the initiation, promotion and progression events in carcinogenesis, mutation of the c-Ha-ras gene appears to be an early, initiating event, and can be mimicked by infection with Harvey murine sarcoma virus or by application of v-Ha-ras DNA to the skin followed by TPA (a caution to those who work with cloned oncogenes and TPA without gloves). Progression from a papilloma to a full-blown carcinoma is commonly associated with amplification or homozygotization of the mutant ras allele and presumably other events, such as loss of suppressor genes.

Biochemistry

Clues about RNA enzymes

from H.D. Robertson

THREE recent papers in *Nature*, one published in May¹ and two published on pages 83 and 86 of this issue²³, present a preview of coming attractions in the study of multiple structural requirements for RNA catalysis. One emerging theme is the dynamic nature of potential RNA active sites, in which the same bases may need to undergo several kinds of secondary and tertiary structural interactions during the reaction.

The ribosomal RNA precursor from *Tetrahymena* has been shown to be capable of self-catalysed cleavage by Cech and his colleagues (ref. 4; see the *News and Views* article⁵ by F. Westheimer). Predictions by Davies *et al.*⁶ suggested a role for certain elements of secondary structure in the processing of the *Tetrahymena* rRNA precursor and other RNAs with Group I introns.

In their new work, Waring et al. point to the importance of a short helix involving the 5' (upstream) splice site of the Tetrahymena rRNA precursor. They used a series of carefully selected mutants in two non-contiguous 9-nucleotide-long regions of the Tetrahymena rRNA precursors: one region includes the 5' splice site; the other, the internal guide sequence (IGS), is part of the intron. These data support the idea that nine Watson-Crick base pairs (bp) form between these two segments to produce a helix which spans the 5' splice site. Waring et al. report. that single or double mutations which interrupt the pairing of this stem block cleavage at the 5' splice site. Compensatory mutations, designed to restore base pairing, lead to cleavage at the correct site. However, in one striking example, a simple transversion of two consecutive

base pairs from one strand to the other reduced the rate of RNA cleavage nearly 100-fold. The authors conclude that the RNA-RNA helix is necessary, but not sufficient, for effective 5' splicing and comment that it is very unlikely that the energy differences between two such closely related 9-bp stems could account for the observed rate differences. Instead. they suggest that "the sequence of (these segments) may play a role in positioning the helix via tertiary interactions between exposed groups on bases in (this) and other parts of the RNA catalyst"

The detailed crystal structures of various model DNA helices support this idea and indicate future directions for experimentation. In addition, the exact role of the 9bp Watson-Crick seondary structure needs to be investigated in more detail, using techniques similar to those of Waring et al. to generate mutations which give aberrant cleavage, rather than no cleavage. Although a helix may help to define the splice site, precision may be conferred by other structural features, with the base pairs needed for stability.

The two papers in this issue address additional aspects of 5' splice-site specifications in Group I introns. One of these', by Garriga, Lambowitz, Inoue and Cech. takes advantage of a previous finding' that certain RNA-catalysed reactions involving the 5' splice site of the Tetrahmyena rRNA precursor can occur in trans. For example, when the dinucleotide CU is incubated with the rRNA precursor in the absence of a guanosine cofactor, normal cleavage at the 5' splice site is not observed; however, the dinucleotide becomes attached to the 3' (downstream) exon at the exact 3' splice site. From this work and the studies of Waring et al.', it appears that the 5' exon remains bound to the IGS even after cleavage at the 5' splice site and that the IGS then positions the 3' splice site for cleavage. Thus, the interaction which forms the 9-bp stem may normally hold the 5' exon in position to attack the 3' splice site, but when cleavage at the 5' splice site (...CU,) is blocked, the dinucleotide CU temporarily disrupts the structure around the 5' splice site and cleaves, adding itself to the 3' exon. This explanation for the effect of CU has been tested by Garriga et al.3.

The authors took a second Group I intron, which has a different sequence in the helix spanning the 5' splice site. In agreement with earlier predictions of Davies et al.", the sequence in the Neurospora mitochondrial cytochrome b intron 1 messenger RNA (CUGGGU, in-stead of the CUCUCU of Tetrahymena) has a complementary region in a segment analogous to the IGS of Tetrahymena. Garriga et al. show that CU promotes cleavage of the Neurospora mRNA precursor to give a 3' exon with GU attached to its 5' end. CU is inactive in this assay. Interestingly,

Galactic strings are stable

Loops of cosmic string may be the seeds of galaxies, as many astrophysicists have suggested, but are they stable and do they last long enough to set galactic formation going? Two theorists from Imperial College, London, have just addressed this key issue, and found that the answer is ves (Copeland, E.J. & Turok, N. Phys. Letts. B 173, 129; 1986).

Initially the strings emerge from the mesh of vortices presumed present after the "phase transition" or "condensation" that takes place when the universe cools through the grand unification temperature - a temperature above which the strong, weak and electromagnetic forces behave as if they had equal strength. The galactic loops are chopped off the mesh about 108 seconds (3 years) after the Big Bang. But the seeding of galactic matter cannot take place before the Universe passes the state of equal matter and radiation density some 10" seconds (3,000 years) later.

Thus the cosmic loops of self-gravitating string, weighing 1,000 tonnes per Fermi (10^{-13} cm) , must last 3,000 years — or the stringy explanation of galactic formation will not work.

Basically, Copeland and Turok set out to show that a complete "seed" loop, which should weigh in at about one-hundredth of a galatic mass and be 30 parsecs long at the seeding time, will not intersect itself on a 3,000-year timescale. Other studies have shown that self-intersecting loops cut themselves in two to form smaller loops, and if this process continued over a timescale short compared with 3,000 years there would be no loops left of the right size to seed galaxies.

In fact, the spectrum of loops that Copeland and Turok start with at 10' seconds has already ironed out simple twisting (as when an elastic band is twisted into a figure eight); the loops they begin with are those left after all initial motions that lead to self intersection have done their work. For the problem in hand, it is necessary to consider perturbations of the remaining strings caused by gravitational effects — reaching sufficiently large amplitudes to cause selfintersection. In principle, cusps can form, for example, that will bite off small loops. Copeland and Turok's calculations show that these effects are negligible over a 3,000-year period, however, so the galactic loops remain effectively stable.

Do the loops remain in present galaxies? No. They steadily shrink, losing mass as gravitational waves, until they vanish in a puff of super-heavy bosons. Looking out into the Universe from our present vantage point, this process was occurring at a redshift of around 100. The furthest known objects are something over a redshift of 3. However, the larger and so longer-lived loops that are postulated to cause the formation of galactic clusters should still be around. They should be hiding in the clusters with lengths of a few kiloparsecs, and masses of the order of that of a galaxy. Robert Walgate

adding trinucleotides to these reactions gives less clear results, leading the authors to point out that "...although Watson-Crick base pairing with the intron binding sites may be an important determinant of the trans-splicing reaction, additional interactions must also contribute to determining the extent of reaction with trinucleotides. Base stacking or non-Watson-Crick hydrogen bonding might allow certain trinucleotides to interact with the normal binding site. Alternatively, the trinucleotide might interact with other, at present unidentified binding sites within the intron". Again we have here base-pairing rules as part of the explanation but additional structural elements are invoked.

In the other paper in this issue' J.W. Szostak synthesized in vitro a 'core' of the rRNA intron containing about 250 internal bases but neither of the splice junctions nor either of the two 9-nucleotide RNA segments whose base pairing I have described here as an important element in cleavage at the 5' splice site. Both these segments are present in a second 'substrate' molecule, a 119-base-long RNA which contains the last 32 nucleotides of the 5' exon and the first 62 nucleotides of the intron, and thus spans the 5' splice site. Neither core enzyme nor substrate RNA is capable of self-cleavage, but gel electrophoresis shows that the core cleaves the substrate accurately to give the expected 5' end of the intron sequence. The interactions between the two molecules studied by Szostak cannot be stabilized by Watson-Crick structural interactions involving the IGS.

Furthermore, Szostak finds optimal cleavage under conditions quite different from those originally characterized by Cech and colleagues' for the self-catalysed splicing of the intact Tetrahymena rRNA precursor. Remarkably, the optimal temperature is 58°C. Szostak concludes "it is likely that the structure of the enzyme is stabilized by numerous tertiary interactions, and that the enzyme in turn stabilizes the structure of the substrate.

Geophysics

A paradigm shift in glaciology?

from G.S. Boulton

Two papers on pages 54 and 57 of this | suggest that part of the west Antarctic ice sheet is underlain by a thin layer of deforming water-soaked sediment. In such areas, the rheological properties of the sediment must largely control the dynamic behaviour of the ice sheet. Until now, most models of glacier flow have assumed that the ice moves over a rigid surface, although this was clearly not true for the great mid-latitude ice sheets of the Quaternary era which flowed over strongly deformed and predominantly soft sediment beds. Perhaps we must now revise our view of the sub-glacial processes which control modern ice-sheet flow, and use the new geophysical data that have been gathered from Antarctica to improve our reconstructions of the Quaternary ice sheets.

The great naturalists of the eighteenth and nineteenth centuries established the fact of glacier movement and observed both internal flow and basal sliding. They were impressed by the erosive power of the debris-studded soles of glaciers, which ground over bedrock to produce smoothed and striated surfaces. Similar surfaces in the mid-latitude lowlands of Europe and North America were thought to support the glacial theory, which asserted that in the recent past these areas had been covered by glaciers of continental scale, similar to the modern ice sheets of Greenland and Antarctica.

Subsequent discussions about glacierbed processes during the early years of this century concentrated on the erosion of rock beds in alpine and highland regions, as the only direct observations of the glacier/bed interface were in natural cavities on the lee-side of bedrock protuberances3. Soft sediment-floored glaciers do not permit such observations as sediment is readily squeezed into incipient subglacial cavities. Thus, it is not surprising that sliding over a rigid bed provided the first quantitative analyses of the processes of basal decollement of glaciers1.5, and that glacier movement was generally viewed as consisting of only two possible components, internal flow and basal sliding. As late as 1979, the symposium of the Glaciological Society on glacier beds was subtitled 'the Ice-Rock Interface', as if the two were synonymous.

Such a paradigm should have been quite implausible to geologists; that it survived so long is an indication of how little note the glaciological community took of the views of geologists. A representative measure of the relative importance of different basal processes has until now been accessible only by the study of the exposed beds of the last mid-latitude ice sheets in Europe and North America (where more than 80 per cent of the surface is overlain by soft deformable sediments) and in the areas exposed by recent retreat of valley glaciers, where sediment beds also predominate. A model in which a glacier slides over a smooth, passive, rigid surface seems quite inappropriate for most of these areas. The existence of widespread glacially induced deformation structures in these sediments has long been known6; such structures are now being more widely recognized, and are often associated with drumlins⁷ (streamlined sediment hills produced beneath glaciers). Recent experiments demonstrate that even relatively coarse-grained subglacial sediments deform readily beneath a glacier and may play a dominant role in glacier movement⁸. It has been further argued that such a mechanism controlled the behaviour of mid-latitude Quaternary ice sheets, with a soft, easily deforming sedimentary substratum permitting high glacier velocities for relatively low driving stresses; rapid responses to changing climate; and fast volumetric growth and decay facilitated by rapid changes in the extent of the ice sheets.

The modern ice sheets of Antarctica and Greenland are thought to be quite different: large, sluggish masses moving by internal flow with fast ice streams radiating through them" and discharge (in Antarctica) up to 90 per cent of the mass flux, although they comprise only 13 per cent of the ice-sheet perimeter. It is assumed that sliding over bedrock occurs beneath these ice streams with a lubricating water layer that decouples the glacier from its bed, thereby reducing friction and permitting fast, low-stress sliding". A predominantly rock bed could result from progressive stripping of pre-existing sediment during the 15 million years of continuous ice-sheet residence on the Antarctic continent.

The recent exciting results from Antarctica reported in this issue1.2 suggest that this picture may not be correct. The results are particularly important in demonstrating the relationship between a possibly drumlinized subglacial sediment stratum and a fast ice stream, and illustrate a geophysical technique that could establish the distribution of their physical properties and their relationship to icesheet dynamics on a wide scale.

Two important implications should be explored: first, that Pleistocene drumlin fields reflect widespread deformation of

soft subglacial sediments, offer little frictional resistance to ice movement and are therefore geological reflections of former fast ice streams; and, second, that soft subglacial sediments are important in regulating the response of the modern Antarctic ice sheet to climate and sealevel changes, a matter of concern even in the short-term future¹³. They may also be important in glacier-surging behaviour.

To explore the implications of subglacial sediment deformation for ice-sheet behaviour we need to understand more about the rapid but sustained deformation of sediments at very low effective stresses. in which dilation is important. Sadly, although such processes are widespread in gravitational flows of many types, adequate flow laws have not been developed and the small strains in most conventional geotechnical experiments make these experiments an inappropriate basis for such laws. Strain rates are strongly affected by water content, so the behaviour of the interstitial water system is of critical importance.

The subglacial zone is different from the decollement zone in most other gravityflow systems, such as gliding nappes and mud flows, in that the glacier sole is a water source, the glacier is an acquiclude and the subglacial water escape pathways are long. Thus, high pore-water pressures need not be transient but can be sustained in a steady state.

The fundamental conceptual difference between analyses of fast low-stress glacier movement over rigid or deformable surfaces is that whereas in the former the surface can be regarded as passive (although it may be temporarily changed by the thickening of a subglacial water film), the strong interaction in the latter requires a coupled analysis of both ice and sediment deformation. Moreover, in coupling the form and structure of the bed with the dynamics of the glacier, such analyses might help to unify glaciology and glacial geology, to the benefit of both disciplines, in a way which until now has been sadly lacking.

A new term in the global carbon balance

Sir-The yearly carbon balance is unbalanced: man-made emissions of carbon dioxide into atmosphere, through combustion of fossil fuels and deforestation, are not fully accounted for by ocean adsorption and measured increase of CO, in the atmosphere. Man can operate powerful disturbances on ecosystems; we will show he can also operate powerful segregation of carbon through a multiplicity of actions which altogether we propose to call "stock and waste" segregation.

Confining ourselves to the most recent estimates of anthropogenic emissions of carbon into the atmosphere, we have a flow of 5.2 gigatons (1015g) carbon per year coming from fossil fuel combustion1 and a flow from deforestation estimated either to be $0.9-2.5\times10^{15}$ g C yr ¹ (ref.2) or $1.6\pm0.8\times10^{15}$ g Cyr ⁻¹ (ref.3). The classical sinks for this total C flow, ocean adsorption (maximum rate 2.5×1015 g Cyr-1) and increase of CO₂ in the atmosphere (measured rate of 2.3×10¹⁵ g C yr⁻¹) are evidently not large enough to accommodate for emissions. We therefore need one or more new carbon sinks.

While revision of older mechanisms is going on and new mechanisms await better understanding and quantification3, we wish to draw attention to a new carbon segregation path whose existence seems to us beyond any doubt.

The fundamental starting point is to recognize that each of the 4,000 million people in the world, within their social and economic structure, is entitled to the possession or use of an array of commodites and services, each having a material base and therefore a carbon content. The ensemble of these posessions, which in developed countries covers an impressive variety of objects, is what we call stock.

In societies recording a continued increase in the standard of living after correction for population growth, stock increases every year.

The carbon content of the global annual increase of stock is a sink that needs evaluation. But commodities and services do not last for ever. Goods must be renewed and new products displace older ones. This creates an enormous flow of materials — the flow of waste.

Whenever waste is not somehow "recycled" but, as in landfilling or dumping, essentially subtracted from natural cycles, its carbon content is segregated for many years. This represents the waste component of our stock and waste segregation mechanism.

Our group is still working on the quantitative evaluation of the stock and waste mechanism in terms of the amounts of carbon that are segregated every year. We can, however, give some preliminary results which show that stock and waste must be taken into account as a term in a correct carbon balance of the world.

As an example of stock increase, we took into consideration the Food and Agricultural Organization4 data on wood production in 1982, during which the wood and pulp and paper industries dealt with 0.7×10^{15} g of carbon. Looking at final uses of this carbon⁵, at least 0.45×10¹⁵g C yr⁻¹ are accumulating in the stock, whereas the rest enters the flow of waste.

Considering the waste contribution to the carbon sink, we note that despite the fact that we are the only producers, our knowledge of global waste production is very uncertain.

Recent data on 10 European countries with a population of 270 million people show that total waste reaches a value of 2 gigatons per year (W. Ganapini, personal communication); a very conservative extrapolation gives a value of at least 7 gigatons for the world.

Heating values for wastes are in the range 800-3,000 kcal kg⁻¹ (ref. 6); an average value of 1,200 kcal kg⁻¹ gives, according to the correlation shown by Tillman⁵, a content of 10% of carbon; assuming that 50% of this waste is subtracted from any substantial oxidation, waste is responsible for the segregation of an impressive amount of carbon, at least 0.35×10^{15} g C yr⁻¹.

Thus the evaluation of just a few terms of the stock and waste mechanism already shows its importance: anthropogenic contribution to carbon subtraction ranks of some 1015g every year. Carbon balance must be accordingly modified.

X chromosomes and dosage compensation

Sir-The contention of Chandra^{1,2} that the primary function of X-chromosome inactivation is one of sex determination rather than dosage compensation is difficult to justify for more reasons than those considered by Lyon3. When examined in the context of the homomorphic sex chromosomes of diploid dioecy and in relation to the X and Y of haploid dioccy, the thesis is untenable.

Sex determination which depended solely on differential inactivation in one or other of a pair of homologues must be recognized as environmental or phenotypic. There is therefore no reason to suppose that alleles related to secondary sexspecific characters would accumulate preferentially in either homologue, for each chromosome could play the role of an X or Y in different individuals. Genetic fixation of sex determination is thus an essential precursor to the evolution of heteromorphic sex chromosomes in an XX/XY or ZŽ/ZW system, and the same is true of the haploid X/Y system of bryophytes'

In many mosses and liverworts there are reports of homomorphic sex chromosomes where the Y of male plants differs from the X of females only in the greater extent of its heterochromatin which, there is evidence to suggest', is facultative. It has been seen in terms of more extensive gene inactivation of secondary female characters in the Y than of male characters borne by the X, characters which it is hypothesized are thus located as a consequence of an earlier monoecious condition45. If sex-determining factors were not chromosomally fixed, both of these homologues would be variously phenotypic X or Y chromosomes. Evolution of heteromorphic X and Y chromosomes, as seen in many families and genera, would not then have followed. Instead, limited but equal erosion of the X and Y would be an expected consequence if crossing-over were excluded from lengths of chromosomes bearing secondary sexual characters', whereas no significant erosion would occur in the absence of chiasma localization.

Motions of the images of atoms

SIR-Howie might have missed an alternative explanation for motions of atom images under the electron microscope in his article "Coulomb explosions in metals" (Nature 320, 684; 1986). The observations made by the groups whose work he reports consist of apparent movement of atoms or columns in gold microcrystals when imaged in the electron

microscope using the rather high electron flux rates required for high resolution. Undoubtedly, there must exist fiendishly high electric field gradients on a highly local level caused by electron-atom collision-induced ionization, and they might be responsible for some positional instabilities of the atoms.

However, one should also consider the effect these charges in the specimen might have on the trajectories of subsequent incoming electrons. They would most certainly distort the optics on a local level. Furthermore, as the charges build up and dissipate — by whatever mechanism(s) the fluctuating local electric fields cause fluctuating local distortions in the microscope's optics (A.P.K. Ultramicroscopy 7, 351-370; 1982). The net result would be somewhat like looking at a photograph lying (face up) on the bottom of a pool of water whose surface is inundated by random ripples. Is it the painting that is undergoing 'convulsions', or is it just its image?

ALEX P. KORN

Biochemistry Department, Weizmann Institute of Science, 76100 Rehovot, Israel

Howie REPLIES-Specimen charging effects certainly can disrupt the imaging process in the electron microscope, giving rise for example to sudden and large image displacements. It seems unlikely, however, that this can account for the majority of the observed apparent changes of structure, particularly changes from single 'crystal to multiple twin and back again.

A. Howie

Legal problems of **Huntington's chorea tests**

SIR—Recent correspondence on the ethics of using a recombinant DNA probe to diagnose Huntington's chorea has not mentioned counsellors' potential legal obligation to provide such a test, regardless of their personal ethical judgement. That the G8 probe does not provide accurate diagnosis is irrelevant here, as all medical diagnoses provide only evidence for disease states, not proof of them. An established genetic screen, fetal karyotyping to detect Downs syndrome, can give good evidence that a fetus is normal, but can also give false negatives for a mosaic fetus1 or for one carrying a Downscausing translocation2, as well as through sampling or laboratory errors. Counselling about the test for at-risk mothers includes mention of these risks, as will analagous counselling for the G8 probe³.

The expectation that mothers over 35 years old will receive fetal karyotyping, with attendant counselling, has recently

acquired a legal standing, with the award of £35,000 damages to Mrs Ayten Yagiz, who sued the City and Hackney Health Authority after giving birth to a Downs syndrome daughter when she claimed not to have been offered fetal karyotyping4. This would appear to establish a precedent for saying that doctors have a legal liability to provide established genetic tests for at-risk mothers. At 40 years old, Mrs Yagiz daughter's risk of Downs was \approx 1% (ref. 5), far less than that facing most parents seeking counselling for Huntington's chorea, cystic fibrosis or other inherited diseases for which cloned probes are becoming available. Other analagous cases are currently awaiting trial. Once cloned probes join fetal karyotyping as an established genetic screen, genetic counsellors may find they have an obligation to use them beyond their present research facilities' ability to do so. This may be a constraint on putting such probes into clinical use.

Is cannibalism all in the mind?

SIR—Behrensmeyer et al. 1 show that trampling of bones in sand can produce marks mimicking cutmarks made by flake tools. They comment that the evidence for meat-eating among early hominids is called into question by this finding.

Putative cutmarks on human bones found at various historical sites, notably at Knossos², have been used to advance the hypothesis that cannibalism was practised in these cultures. The finding of Behrensmeyer et al. raises the possibility that this hypothesis, too, is unfounded and strengthens Arens's contention that apparent evidence for ritual human cannibalism is in fact a psychological phenomenon of anthropologists rather than a dietary phenomenon of 'barbaric' civilizations.

Linkage between the nation states

Sir-The 'self-thinning' rule of plant ecology^{1,2} states that as communities of plants mature, increases in the mean mass per individual plant (W) tend to be accompanied by decreases in the number of plants per unit area (N), and in particular

 $\log W = A + B \log N$

where A and B are constants. If B took the value -1 then decreases in N due to selfthinning would be exactly matched by increases in W and the mass of standing crop per unit area (=W.N) would be constant (= A). In practice^{3,4}, B tends to take values close to -3/2, so that

 $\log W = A - 3/2 \log N$

Hence

 $\log W = 3\log(W.N) - 2A$

and the standing crop increases with W. Denness⁵ suggests that the '-3/2 rule' applies to the distribution of size and density between the states of Europe; and hence he argues that if the total population is to expand the number of nation states in a given area must decrease. The evidence rests on a log-log graph in which W was equated with nation size (population) and N with 1/(national area) (that is, with number of nations per unit area)6. The graph resembled a scatter plot, but the addition of a grid of lines of slope -3/2yielded some apparently meaningful associations between nations6. I suggest that any resemblance with the -3/2 rule' of plant ecology is fortuitous.

The figures for population density of

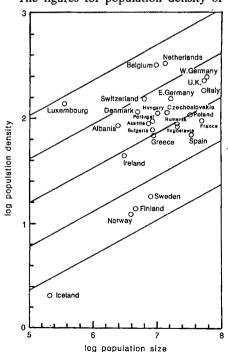

Fig. 1 A plot of log₁₀ population density (people per km²) against log 10 population size (people per nation). The added lines have a slope 1/3.

different nations conceal substantial fluctuations; in cities the number of people per square kilometre may be greater than in rural areas by several orders of magnitude. It seems reasonable to suppose that bigger nations will support bigger conurbations than small, and that hence the mean population density for a large nation may be greater than for smaller ones. If this were so, then nations of similar character might fall into alignment on a graph of log population density on log nation size (Fig.1). They would also give apparently meaningful alignments in graphs of log nation size (W) on log area (= 1/N) (ref. 6). In particular, if the slope of the graph of log population density (=W.N) on log nation size (=W) is approximately 1/3, then the slope of the graph of log nation size (W) on log area (=1/N) will be approximately 3/2; but this does not mean that people obey the same 'laws' of nature as plants. The alignments, I suggest, are attributable to the factors that control the aggregation of people in cities and not to any inherent tendency for the nation states within a continent to undergo 'self-thinning'.

Is Classic Coca-Cola the real thing?

SIR-During 1985, the Coca-Cola Company discontinued production of its "old" Cola-Cola soft drink and introduced the New Coca-Cola. In response to public demand for the "old" Coke, the Coca-Cola Company began marketing the Classic Coca-Cola. Consumer complaints about difference in taste between the Classic and "old" version were supported by claims from both the Sugar Association, Inc. and Newsweek that the Coca-Cola Company had discontinued the use

of sucrose (table sugar) in 1984. Since the Classic Coca-Cola container bears the words "Original Formula" and the major ingredient other than carbonated water in both the Classic and the New Coca-Cola is "high fructose corn syrup and/or sucrose", while that of "old" Coca-Cola was "sugar", we determined the sugar content of the newly introduced drinks to compare them with our previous analyses of "old" Coca-Cola.

Sugar analyses, using a gas-liquid chromatographic procedure3, confirm claims12 that neither Classic nor New Coca-Cola contain sucrose, whereas in 1983 we found that "old" Coca-Cola contained 4.7% sucrose (Table 1). There was also no sucrose in what we refer to as "transition" Coke since it was produced just prior to the introduction of the New Coca-Cola on 23 April 1985. Total sugar content of "transition", Classic and "old" Coca-Cola was very similar, but the new version contains about 10% more total sugars than any of the others.

As noted above, the Coca-Cola labels now read "high fructose corn syrup and/or sucrose", thus eliminating the use of the word "sugar". Recently the cereal industry made a similar move by eliminating the word "sugar" from the name of cereals and from its advertising even though the product and the sugar content remained unchanged4. Why discontinue the use of the word "sugar" which most consumers understand to be table sugar? Because health conscious consumers often associate sugar with obesity, diabetes mellitus, heart disease and dental caries5

Sucrose (table sugar) has long been considered the mortal enemy of the teeth by virtue of the amount ingested and its pattern of use6. What impact upon dental health should one expect from the replacement of sucrose with fructose and glucose in soft drinks? Such an assessment is impossible at the present time because there are no definitive studies which demonstrate clearly the contribution of sucrose, fructose, or glucose in soft drinks to incidence of dental caries.

If sucrose is the arch criminal of dental caries as has been claimed, one might expect a decrease in the incidence of

Table 1 Sugar analysis of Coca-Cola by gas-liquid chromatography

			Sugar content (%)				
Product (code)	Date of production	Date of analysis	Fructose	Glucose	Sucrose	Total	
"Old" (032483289)	24 Mar. '83	12 Apr. '83	3.3±0.1	2.9±0.3	4.7±0.3	10.9	
"Transition" (no code)	Early 1985 before 23 Apr. '85	13 Sept. '85	6.3±0.1	4.5±0.1	0	10.8	
New Coca-Cola (061485189)	14 June '85	13 Sept. '85	7.0±0.1	4.9±0.1	0	11.9	
Classic Coca-Cola (K8H22)	22 Aug. '85	13 Sept. '85	6.3±0.1	4.6±0.1	0	10.9	

Sugar contents are mean ± standard deviation of triplicate determinations.

dental caries due to the elimination of sucrose from the soft drinks. However, if fructose and glucose are as cariogenic as sucrose in soft drinks, one might expect an increase in the incidence of dental caries due to an increased amount of total sugar as seen in the New Coca-Cola. What effect, if any, the changes will have on consumer demand and/or health remains to be seen.

Are we all out of Africa?

SIR-Additional information on world population distributions of human marker genes, such as that provided by Wainscoat et al. for five closely linked polymorphic restriction enzyme sites in the β -globin gene cluster, is always welcome. One must agree, on the basis of the restriction enzyme evidence provided, that there is a clear distinction between African and Eurasian populations, an opinion in accord with at least some other genetic studies. While Wainscoat et al. are nominally cautious about a second proposition, stating that their data are "consistent with" the notion that anatomically modern man (Homo sapiens sapiens) arose in Africa and subsequently spread to Eurasia and the Americas, it is difficult to deny that their results will be taken as "new evidence that the origin of modern man lies in Africa"2.

frica"². R 440 A close scrutiny of this new evidence is especially important because of its potential value when the prime archaeological rationale for asserting great antiquity for South African H. s. sapiens at Klasies River Mouth and Border Cave is not conclusive^{3,4}, has been challenged⁵, and the H. s. sapiens status of the Omo specimens from Ethiopia has been questioned.

On the basis of a sample perhaps more limited than the authors concede. Wainscoat et al. note that three haplotypes (the specific sequence of appearance [+] or absence [-] of the five sites along one chromosome), namely (+---), (-+-++) and (-++-+), are common in Eurasia, while a fourth, (---+), is common in Africa and absent elsewhere. A punctuationalist evolutionary explanation is advanced: that a 'small' founder population of H. s sapiens migrated from Africa to Eurasia, losing the characteristic African haplotype (----+) en route to Eurasia by genetic drift. Present-day 'new' haplotypes, that is, other than the four common haplotypes assumed to "predate the racial divergence", may in most instances "be derived from the four common ones by single crossovers".

Forty years ago Fisher⁷ first applied the crossover hypothesis in human genetics to the rhesus (Rh) blood group system, suggesting less common Rh types "are maintained [our italics] by such occasional cross-overs" of the more common types in the British population. Wainscoat et al. propose a similar origin for haplotypes (+--++) and (-++++) in Melanesia and Polynesia, presumably from (+---) and (-+-++) for the former and (-+-++) and (-++-+) for the latter. Since the Eurasian recombinants' frequencies are 2.0% and 1.1%, while the putative parental frequencies are 65.6%, 19.8% and 6.7%, the explanation has distinguished precedent. But in Africa, which Wainscoat et al. do not discuss, using analogous logic, (-+--+) should be a recombinant form of the common haplotypes (-+-++) and (-++-+). Curiously, this recombinant's frequency in Africa is 19.7%; the frequencies of the presumptive parental types in Africa are 9.8% and 1.6%. In fact, the recombinant's frequency in Africa is the same as the frequency of the second most common haplotype, (-+-++), in Eurasia.

We are certain that Wainscoat et al. would agree that their data are limited and interpretations preliminary. Nevertheless, we believe that unwarranted credence accrues to the sequence of events they outline, however hedged, when it is presented simply as the loss of one haplotype in a founder population's move from Africa to Eurasia. It ignores the need to interpret the 20% frequency of an apparent recombinant form in Africa, and the ostensible reduction of all three common haplotypes in Africa: to 4.9% (+----), 9.8% (-+-++) and 1.6% (-++-+) from the current Eurasian frequencies 65.6%, 19.8% and 6.7%, respectively. Jones and Rouhani' in their imaginative "Out of Africa" scenario see no need to explain how, for example, the common haplotypes (+---), (-+-++) and (-++-+) went from 75% in their proposed "ancestral African populations" to their current combined frequency in Africa of 16.4%.

Our view is not that the data are incom-

patible with the proposition that H, s, sapiens evolved in Africa and moved to Eurasia, but that they do not provide any evidence for that, and are, in fact, equally compatible with the position that H. s. sapiens originated in Eurasia and migrated to Africa, or perhaps other alternatives. It could be argued that in Africa not only (-+--+) but also the common haplotype (---+) are recombinants: Wainscoat et al. suggest that (---+) in Papua New Guinea may have arisen through recombination, even though it could not be by a single crossover between any of the three common Eurasian haplotypes. If so, one might ask whether the African population, characterized (80%) by thus possibly recombinant forms, is more likely to be ancestral or derived. We believe the genetic data provided by Wainscoat et al. are at the very least a tossup in terms of African or Eurasian H. s. sapiens origins, and that the genetic distance analysis presented in their Fig. 1 dendrogram, an analytical approach notorious for its pitfalls8, speaks basically to what is not at issue, namely that the Eurasian and African frequencies are very different

It should not be forgotten, as Antonarakis et al.9 note, that while the mechanism for producing nonrandom association of DNA sequences located in the region of the β -globin gene cluster is unknown, possible explanations include selection pressure for specific DNA sequences within the region. Selection and migration may be a better model for the observed data than reconstructions based on an assumption of drift and migration alone. with direction of migration emerging from, rather than imposed on, such a study.

WAINSCOAT ET AL. REPLY—We agree that data on β-globin gene haplotypes¹ should be analysed in relation to their evolutionary implications for human populations. Giles and Ambrose do not question our conclusion that there is a major division of human populations into African and Eurasian groups, but they raise the im-

portant issues as to which haplotypes and indeed which populations are ancestral. We believe that a small number of common haplotypes predated the racial divergence and that many of the rare haplotypes have since arisen by crossovers between them. Giles and Ambrose emphasize the fact that the second most common haplotype in Africa (-+--+) could result from recombination between two haplotypes (-+-++) and (-++-+) which, although common in Eurasia, are relatively uncommon in Africa. It is, however, also possible that this African haplotype (-+--+) is derived from the most common African haplotype (---+) by a single point mutation rather than by recombination. Fortunately, these questions may be answered by sequence analysis of the haplotypes as demonstrated by the elegant study of the 'R' and 'T' haplotypes in a segment of the β-globin gene cluster2.

Of course, the data on the B-haplotypes taken by themselves do not prove an African origin for modern man. Nevertheless, this hypothesis is consistent not only with fossil evidence³, but also with the available molecular data. The two lines of evidence that are emerging from DNA analysis of human populations are, firstly, genetic distance analyses, based on allele and haplotype frequencies, which show a distinct African lineage^{1,4}, and second, data indicating a greater nucleotide sequence diversity at particular loci in African populations^{4.5}. Our β -haplotype data and more recent population data on a a-globin haplotypes⁶ both suggest greater diversity in African populations, making an African origin for man more likely than one in Eurasia.

These observations are preliminary and will require confirmation by analysis of other world populations and investigation of many other loci. Nevertheless, if they are corroborated, it would be very difficult to postulate that Eurasian populations were ancestral to African populations. Much more likely, as Giles and Ambrose put it, "Out of Africa".

Behind the bifocals

Roy Porter

Franklin of Philadelphia. By Esmond Wright. Harvard University Press:1986. Pp. 404. \$25, £21.25.

Benjamin Franklin is safely installed in one of the most prominent niches in science's pantheon. An early dabbler in experiments, the Philadelphia printer had put electrostatics on a new footing by the time he was forty. He advanced the theory that electricity constituted a single fluid, explained the conservation of charge, and introduced the concepts of plus and minus, positive and negative. But harnessing that terrifying force was no less vital to him than understanding it. Through demonstrating by experiment that lightning was electrical, Franklin was able to pioneer the lightning conductor (though George III stubbornly refused to employ the gadget of the Yankee rebel). And by explaining the charges of the Leyden Jar, he anticipated times when electricity would constructively lie at man's service (he himself tried shock treatment in cases of paralysis, but doubted the lasting efficacy of electrotherapy). As thumbnail sketches go, it is accurate enough to see Franklin as the founder of modern electrical science.

Yet he was also a scientific all-rounder with a ready gift for invention. He studied the Gulf Stream, developed bifocal glasses, rationalized spelling and fireplace design, and even improved the rocking-horse (how like his English contemporary Erasmus Darwin!). A jack-of-all-trades, it was his rare good fortune to be master of many.

But Franklin was never more than a part-time scientist. And it is the achievement of Esmond Wright's polished biography that, recognizing that Franklin's scientific career has already been fully analysed, he has concentrated on painting a rounded portrait of all the facets of this supremely versatile and talented man. Franklin as business-man, journalist, raconteur, politician, diplomat, sage, architect of American independence and man of the world: all are here. Not least, we see Franklin as author and embodiment of the American dream. His is an extraordinary tale of self-help and hard work leading to success.

Born in 1706 of poor immigrant stock, Franklin trained as a printer; publishing led to writing, and Franklin soon won himself renown as the author of *Poor Richard's Almanac*, full of wise saws for getting on ("Early to bed, early to rise..."). By mid-life he was wealthy enough to retire from business. Ever energetic, he threw himself into public

affairs. Prominent in founding the American Philosophical Society and what was to become the University of Pennsylvania, he was elected to the colony's assembly in 1746. Soon he found himself sent to England, in effect as ambassador for the Colonies, at precisely the moment when relations between them and Westminster were going sour.

The canny Franklin was all for compromise not confrontation. In any case, he was profoundly Anglophile, envisaging America's greatness lying within a glorious global British Empire. But it was not to be. Extreme counsels prevailed on both sides of the Atlantic, Parliament became intransigent and Franklin found himself forced to abandon pragmatism for patriotism. Becoming the elder statesman of the War of Independence, he ensured that France entered the war on the rebels' side, helping to tip the balance. He was sure of American victory, for there was no hold-

ing back progress. New Worlders were ambitious, no-nonsense and free from the fossilized forms of the Old. Combining realism and optimism, Franklin nailed his colours to the mast of the future.

Scientific biographers all too often forget that their subjects are flesh and blood creatures, with lives outside the laboratory. Franklin certainly was, with his eve for women, a taste for old madeira and an unquenchable thirst for life. Above all. Wright shows how science and politics were inextricably linked in Franklin's outlooks and career. Natural science was the technique of improving man's material lot; politics the art of social progress. "O that moral science were in as fair a way of improvement", lamented Franklin. "that men would cease to be wolves to one another, and that human beings would at length learn what they now improperly call humanity".

Amen. Ben Franklin was full of such maxims, no less wise for being homely. Anyone wishing to penetrate behind the bifocals, into the urbane mind of the first and greatest of the Yankee scientists, cannot do better than to sample this feast of a biography.

Roy Porter is at the Wellcome Institute for the History of Medicine, 183 Euston Road. London NWI 2BP, UK.

Only natural?

Alastair Fitter

The Oxford Dictionary of Natural History. Edited by Michael Allaby. Oxford University Press:1986. Pp.688. £20, \$29.95.

The two essentials of a good dictionary are comprehensive coverage of its subject, and accurate and up-to-date definition of terms. The editor of *The Oxford Dictionary of Natural History* (who, incidentally, has only edited it, and not provided definitions) states that it takes in the "earth sciences, atmospheric sciences, genetics, cell structure and function, biochemistry, parasitology and other disciplines". Curiously missing from this list is ecology, once described as scientific natural history.

The natural history component is in fact supplied by copious and extensive references to taxa of living organisms, complete (apparently, and I found no exceptions) down to family level and with many genera and species of greater than average interest included as well. These entries make up at least half of the total, and they will, I suspect, be of great value both to professional biologists and to the book's intended audience: students and amateur naturalists. I know of no equivalent compilation with coverage ranging through

bacteria to fungi, plants and animals, and both the choice of taxa and the comments in each entry seem appropriate.

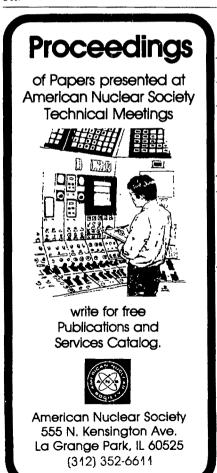

But the list of disciplines included, with biochemistry and cell structure and function among them, worries me. How many amateur naturalists want to know about the sliding-filament theory of muscle contraction? And, curiously, though many enzymes have entries to themselves, those that might interest naturalists, such as esterases (for their importance in electrophoretic studies) and ribulose bisphosphate carboxylase (the commonest protein in the world) do not appear. Surely natural history is not concerned with mechanisms at the infra-organismic level, and biochemistry and cell biology are out of place in a book such as this. Conversely, the word "history" is used here in the Aristotelian sense, a general account of natural phenomena; so it is right that the earth and atmospheric sciences should be represented.

What, then, of the details? Here I can only turn to the areas I know best. Generally, the definitions seem good, though I would quibble with some (for example those of *fitness*, *polyploidy* and *red light*), and others seem a little dated (under *succession* no mention is made of concepts such as facilitation). But in a book of over 12,000 entries it is pointless to pick out one or two individual definitions. More disturbing is the absence of some terms:

mimicry (unless you look up Müllerian), CAM (though C, photosynthesis is in), Red Queen, the MacArthur-Wilson. hypothesis (though island biogeography makes it). Clements (though Gleason gets a mention). There is in this a certain lack of consistency. Some entire fields seem simply to have been overlooked: for example, a whole suite of terms in common use in the study of plant-breeding systems (geitonogamy, gynodioecy, incompatibility) are undefined, at least in this sense. Similarly the coverage of statistical terms is poor and uneven: correlation appears, but analysis of variance, chi-squared, degrees of freedom, regression and t-test do not.

It is surprising that a dictionary of natural history should seem weakest in its coverage of ecology and evolution, but perhaps this is because ecology, though rich in jargon, has yet to develop a stable vocabulary. I doubt whether this dictionary will enable amateur naturalists to understand the American Naturalist, but it contains a wealth of useful taxonomic, geological (in the broad sense) and atmospheric information. Hidden away in it, too, are some real gems: apparently you do get blue moons, particularly in China!

Alastair Fitter is a Lecturer in the Department of Biology, University of York, York YOI 5DD, UK.

Policing the paper chase

Stevan Harnad

A Difficult Balance: Editorial Peer Review in Medicine. By Stephen Lock. Nuffield Provincial Hospitals Trust, London: 1985. Pp. 172.*

How grave a problem is peer review? The answer is likely to depend on which of the following propositions one judges to be closer to the truth: (i) most of the scientific research that appears in print is significant and essential to the progress of science; (ii) most of it is neither significant nor essential. There is evidence in favour of both propositions. Most papers have minimal content and are rarely or never cited or built upon. On the other hand, it is not clear that high-quality work could be done in a less permissive atmosphere; so, the wheat may always be proportional to the chaff.

Propositions (i) and (ii) have very different implications for the problem of peer review. If most published work is significant, then it is critical what one accepts and rejects for publication, and how: the consequences of the two types of errors, false negatives (failures to accept important papers) and false positives (failures to reject wrong or trivial papers), loom large. If, instead, most published work is insignificant (which is equivalent to saying that most work is published), then the repercussions of the two types of errors diminish considerably.

What is peer review? In his welldocumented and informative survey of editorial procedures in the biomedical sciences, Stephen Lock, editor of the British Medical Journal, indicates that it is the relatively recent practice of having work formally (and usually anonymously) evaluated by fellow-scientists. Publication and funding decisions are then made on the basis of the recommendations of these "referees". But whereas the institutionalization of the practice may be recent, it seems apparent that human judgement (not necessarily on the part of peers) has always entered into publication and funding decisions, even in the good old days when just about all research was published and funded.

The funding situation has unfortunately become much more competitive (and perhaps here a more serious problem is developing), but it is still true that just about everything is being published. The

only question is where. Peer review seems to serve to channel the higher quality work towards the more prestigious and widely read journals: in effect, it serves as a selective filter for the beleaguered reader who must keep up with the glut of literature.

Why is there a literature glut? Lock indicates that the emphasis placed on publication-counts in decisions about appointments, promotion and even funding has favoured the strategy of publishing as much as possible, in minimal increments. He sees it as an urgent problem — though not strictly one of peer review - to stem this swelling tide of superfluous publication, perhaps by permitting individuals to publish only five articles per year. This suggestion is not as capricious as it may sound, and would certainly be one way of improving the ratio of quality to quantity in the literature. An intermediate measure would be to place more emphasis on citation-counts than on publicationcounts. Unfortunately, however, both of these are merely black-box, quantitative criteria.

Peer review looks into the black box. but how discerning is it? False positives are easier to identify than false negatives, and Lock surveys some of the prominent cases of error and fraud that have found their way into print. Yet their proportion seems low, probably because science is cumulative and self-corrective, and one cannot build much on a defective foundation (although Lock does give an alarming example of an over-hasty clinical application of a false toxicological report, which had serious consequences for public health). Proposition (ii) — that most published work is inconsequential - suggests another reason why false positives may not represent such a critical problem.

But even proposition (ii) implies that false *negatives* may be a problem. A conservative tendency (and perhaps a regression towards the average) in collective endeavours puts disproportionate innovativeness at something of a disadvantage among peers, and this is most likely to occur at the high end of the spectrum of significance. Yet quackery and dilettantism need to be filtered out too, and most articles do benefit from the revision they have undergone through peer scrutiny.

False positives and negatives are optimization problems, and Lock offers many useful ideas for investigating and improving the peer-review system. One wonders, however, about the generality and representativeness of conclusions based largely on the biomedical and social sciences. The picture may be quite different in the physical sciences and mathematics (which have lower rejection rates and perhaps different evaluative criteria), and may even vary with whether research is experimental or theoretical, pure or

applied, specialized or interdisciplinary.

Nevertheless, Lock's survey and recommendations are welcome. They include a suggestion that in special cases it would be useful to complement closed peer review with the publication of open peer commentary. I cannot but second this, particularly as 39 of the 281 items in Lock's reference list come from a controversial peer-review study that appeared in the peer-commentary journal I edit — a study whose themes, Lock writes, "run through this monograph as a leit-motiv. almost as obsessionally (to mix my metaphors) as the Suez canal ran through Lady Eden's drawing room during the 1956 Suez crisis".

There is an interesting parallel between beliefs about "the peer review system" and beliefs about "the scientific method". Those who favour proposition (i) tend to worry about biases and conspiracies that could impede the ideal march of progress. Those, like myself, who lean towards (ii), feel that it's more a matter of trying to reduce inefficiencies in vet another very human domain of endeavour.

Hormonal activity

Michael J. Brownstein

Neurobiology of Vasopressin. Edited by D. Ganten and D. Pfaff. Springer-Verlag: 1985. Pp.203. DM 98.

Vasopressin. Edited by Robert W. Schrier. Raven:1985. Pp.577. \$104.50.

THE history of research on vasopressin goes back almost a hundred years, to 1895, when Oliver and Schafer showed that mammalian pituitary extracts had pressor (blood-pressure-elevating activity). Three years later Howell demonstrated that the factor responsible resided in the posterior or neural lobe of the gland. Subsequently, Dale found that neural lobe extracts possessed oxytocic activity (that is, they contracted uterine smooth muscle) and von den Velden showed that these extracts could inhibit diuresis as well. In the course of the next 20 years it was established that the oxytocic and pressor-antidiuretic effects were mediated by separate factors, oxytocin and vasopressin, respectively. These were finally purified, characterized and chemically synthesized by du Vigneaud and his colleagues in the 1950s.

Early workers found it difficult to believe that the posterior pituitary could elaborate hormones. Cytologically it is very different from most glands. The revolutionary discovery by Bargmann and Scharrer in 1951 that the neural lobe is part of a neurosecretory system resolved this problem. The vasopressin in the neural lobe is actually in axons and nerve terminals provided by hypothalamic neurones: vasopressin is released from these nerve terminals into blood vessels to act on its peripheral targets.

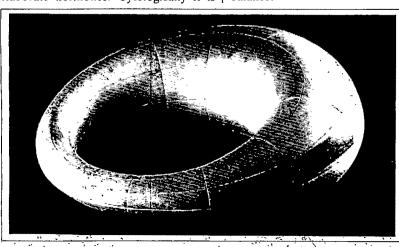

Neurobiology of Vasopressin, the fourth book in a series on current topics in neuroendocrinology, contains five chapters contributed by a total of nine authors. It nicely outlines the research work on vasopressin of the past decade, a period during which many other neuropeptides have come under careful scrutiny. The amino-acid sequence of the vasopressin precursor is now known and its gene has been characterized. Cells that make it have been visualized immunocytochemically. (Many of these lie outside the nuclei that project to the posterior pituitary and seem to be involved in central regulation of autonomic function; surprisingly, some vasopressin-positive cells are present in peripheral tissues such as the adrenal and ovaries.) Steps are being taken towards understanding how vasopressin's synthesis is regulated, and how the afferent inputs to the cells that manufacture it control its production and release in response to changes in water balance.

In spite of the fact that vasopressin's name derives from its effects on blood vessels, these effects are only seen at high dose levels and its cardiovascular effects attracted little interest for many years. This is no longer the case. It is now understood that vasopressin's vasoconstrictor effects are masked by some of its other actions: facilitation of the inhibitory actions of baroreceptive pathways on sympathetic vasomotor activity, and depression of renin secretion. Appropriately, therefore, a large part of Vasopressin, the second book reviewed here, is given over to descriptions of the hormone's interactions with central and peripheral baroreceptor systems and regional vascular beds. Also included are sections devoted to the cellular action of vasopressin, vasopressin antagonists, osmoregulation of drinking and vasopressin secretion, neural control of vasopressin release, and the role of vasopressin in producing pathological states.

While many of the individual chapters are very good, the overall organization of the book leaves something to be desired. Those new to the field would have profited from introductory descriptions of vasopressin's structure, biosynthesis, site of production and release, actions and receptors. It is only in the context of this background information that subsequent chapters, which deal with intricate physiological and pharmacological experiments, can be appreciated.

For this reason, I would suggest that readers should tackle Neurobiology of Vasopressin before attempting to digest its larger sister volume; in particular, the chapters on volume and cardiovascular regulation in Ganten and Pfaff's book will provide helpful overviews for those attempting to get their bearings on the vasopressin literature. Both books are worth studying, and that neither of them is quite up to date might be seen as a plus point; work on vasopressin is moving along very quickly.

Michael J. Brownstein is in the Laboratory of Cell Biology, National Institute of Mental Health, Bethesda, Maryland 20205, USA.

ONE of the pleasanter branches of nineteenth-century mathematics was the study of curves and surfaces in space. In order to examine and communicate their properties, geometers built three-dimensional models which frequently possess that interplay of simplicity and complexity, of order and chaos, which characterizes the best abstract art.

The illustration shows one of the "cyclides of Dupin", a class of surfaces whose lines of curvature are all circles or straight lines. Photographs of 132 such models, with mathematical commentary, have been collected into a two-volume work, Mathematical Models, edited by Gerd Fischer and published by Vieweg, Wiesbaden, FRG, as part of their two-hundredth anniversary celebrations. In Britain, the books are distributed by Wiley; in the United States, by International Publishing Services, PO Box 230, Accord, Massachusetts 02018.

Men and machines remembered

J.M.M. Pinkerton

Memoirs of a Computer Pioneer. By Maurice Wilkes. MIT Press:1985. Pp.240. \$19.95, £19.95.

ELECTRONIC computing and communications technologies are of indisputable social and economic importance. To anyone in the field, and many outside it, the history of their development recorded by one of the innovators must be of the greatest interest. Professor Wilkes's book, part of a historical series published by MIT Press, is therefore likely to find a large and receptive audience.

About half of the book deals with the author's family background, his education, his radio research at the Cavendish Laboratory before the war under J.A. Ratcliffe and at the Mathematical Laboratory in Cambridge, and his varied wartime activities as a government radar scientist. All this experience was in fact invaluable, not only because many of the electronic techniques used for radar were readily adapted to the design of early computers, but because Wilkes had become familiar with problems and methods of computation for which computers were suitable.

A fascinating chapter describes the conception, planning and successful construction of EDSAC 1 in the Mathematical Laboratory in the years 1946 to 1949. Wilkes records this in such straightforward terms as almost to belittle the achievement. He carefully acknowledges where due his indebtedness to others for inspiration — to John von Neumann; to speakers on the course at the Moore School of the University of Pennsylvania in 1946, when a variety of techniques were proposed to build a working computer; to the Eckert-Mauchly report proposing a design for EDVAC; and, especially, to Douglas Hartree.

As the series editors say in their foreword, Wilkes aimed not merely to build a machine that would work, but also to investigate programming as an art and an intellectual process applicable to problems, for example in physics, whose numerical solution called for extended computation. While scientists at Cambridge were using the differential analysers, originally developed by Hartree at Manchester and already installed in Wilkes's laboratory, it was anticipated that EDSAC would be faster and better in all respects. With Wheeler and Gill, Wilkes was the first to write subroutines and incorporate them in programs, and a library of subroutines was quickly assembled for programmers' use. Even before EDSAC was finished, much thought had been given to feeding decimal numbers in and out; for scientific work, the simple paper tape and teleprinter combination adopted was reasonably well matched to EDSAC's arithmetic speed.

Remarkably soon after EDSAC successfully ran programs, Wilkes started to teach others how to develop them, very much in the tradition of the Cavendish Laboratory. Ratcliffe, whose guidance in his earlier career Wilkes acknowledges, used to say that no research was complete until it had been taught, not just published. The course first given in 1950, was the basis of the first book on programming ever to appear - The Preparation of Programs for an Electronic Digital Computer, with Special Reference to the EDSAC and the Use of a Library of Subroutines (Addison-Wesley, 1951), which was re-printed by Tomash and MIT Press in 1982.

After starting an informal computing service, based on EDSAC, for the whole University, Wilkes began to design EDSAC2. This was to be a parallel machine retaining the ultrasonic memory, though in the event core memories were invented in time. A major innovation was microprogramming, a concept Wilkes first described in 1951 and which, of course, has since had a profound influence on computer design.

In the book Wilkes refers to the key contribution he made in the early 1950s to the LEO project (Lyons Electronic Office, the first computer built specifically for clerical work) and later, obliquely, to his present job with Digital Equipment Corporation. But he says little about the guidance he gave as Director of the Cambridge Computer Laboratory until he moved to the United States in 1980, not only to his students but to anyone else who asked for it, as many did.

The book concludes with chapters on more recent developments on both sides of the Atlantic, with many of which Wilkes was involved (for example use of capabilities and the Cambridge Ring LAN). In sum, this is a straightforward personal account, clearly and readably told; it represents a notable contribution to the early history of ideas and practice in digital computing, as they have evolved throughout the world.

High-resolution sedimentary record of a geomagnetic reversal

J.-P. Valet, C. Laj & P. Tucholka

Centre des Faibles Radioactivités, Laboratoire mixte CNRS-CEA, Avenue de la Terrasse, Parc du CNRS, 91190 Gif sur Yvette, France

A detailed study of a geomagnetic reversal shows that during the transition the geomagnetic field undergoes both short-and long-term fluctuations. The first are thought to be linked to the reversal process; the second are present with the same time constants both before and during—the reversal. This suggests that the secular variation, at least in its longer-period terms, is not affected by the reversal of the main field. This feature has important consequences for the validity of the frezen-flux approximation.

SEVERAL recent publications have demonstrated that palaeomagnetic studies of reversals may contribute to a better understanding of the mechanisms of the geodynamo. For example, a comparison of the trajectories of the virtual geomagnetic pole (VGP) during the Brunhes-Matuyama transition, as seen from two different sites¹, has led to the conclusion that the geomagnetic field shows a predominantly non-dipole behaviour during a reversal. Other studies have demonstrated that, although axisymmetrical terms certainly play a key role in the morphology of the transitional field, large non-zonal terms are also present²⁻⁴. Various models for reversals have been proposed to account for these observed features^{5,6}.

With a few exceptions⁷⁻⁹, however, the published records are not sufficiently accurate to provide detailed information about the precise geomagnetic variations occurring during a reversal, often because of a lack of intermediate directions, or because of bad stratigraphic control of the different samples. Here we describe the results obtained from a reversal recorded in a sequence of Tortonian marine clays near the village of Skouloudhiana in the Khania province of western Crete. We have already described^{10,11} some of the main characteristics of the different reversals recorded in this section and in another nearby section at Potamida. Here we consider only the upper reversal in Skouloudhiana (KS 06 in the previous work), which has been studied in great detail. About 100 additional transitional palaeomagnetic directions have been obtained and the results analysed with suitable mathematical techniques.

Geological setting and sampling

The section at Skouloudhiana comprises 54 m of homogeneous blue-grey marine clays. In the sampled portion of the section, which is well-exposed, there is no evidence of faults or slumped beds. The bedding plane is very nearly horizontal, so no tilt correction has been applied to the results. Previous biostratigraphic results have established that the section belongs to the Upper Tortonian stage¹², and correlation with the geomagnetic polarity timescale¹² gives an age of 5.87 Myr for the upper R-N (reverse- to normal-polarity) sixth reversal (upper part of epoch 6).

In a dense sampling programme during two field trips, 295 cores (6-15 cm long) were collected over a stratigraphic height of 4.7 m, comprising the entire transition zone and also levels outside the zone. The cores were cut in the field into 22-mm samples.

Very careful attention was paid to the determination of the exact stratigraphic position of the samples. Stratigraphic reference levels were marked every ~20 cm on the surface of the section, and the position of each core was measured with respect to these levels. Measurements of core positions with respect to different reference levels yielded identical results to within 0.5 cm: this value was then taken as an estimate of the error. Precise stratigraphic marks and photographic records have

allowed us to correlate the stratigraphic position of cores drilled during the second field trip with those obtained during the first, with almost the same accuracy. The final stratigraphic position of the different samples obtained from the cores was calculated using a computer program which took into account the usual orientation parameters of the cores, their stratigraphic position, and even the width of the diamond saw used to cut the samples.

The result of the sampling programme was an almost continuous stratigraphic succession with several specimens at each horizon, so that different experiments could be performed on samples from the same stratigraphic level.

Sedimentology and magnetic mineralogy

Although the good magnetic properties of the clays of the Skouloudhiana section had already been established¹², further analyses were made in the stratigraphic interval corresponding

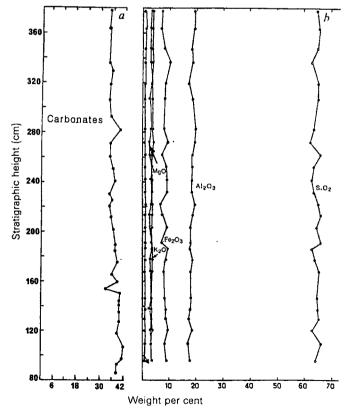

Fig. 1 Evolution of characteristic sedimentary parameters as a function of stratigraphic height. a, Variations of the carbonate fraction expressed in percent of the total weight; b, variations of the major elements expressed in weight per cent of the residual carbonate-free fraction.

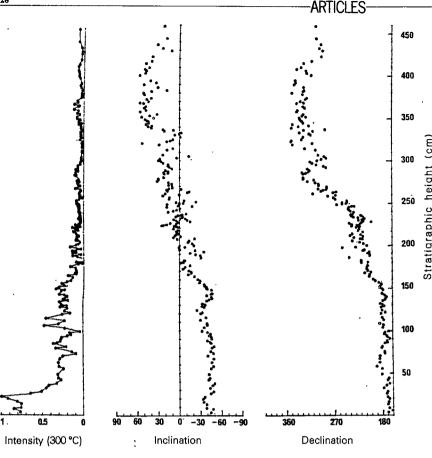

Fig. 2 Records of the intensity (after heating at 300 °C), declination and inclination, plotted against stratigraphic height. The results have been averaged for 10 pairs of samples separated by less than 0.5 cm.

to KS 06. Particular attention was paid to those parameters whose possible variation with stratigraphic height could be an indication of large perturbations or changes in the sedimentary regime.

At 34 levels regularly spaced over the KS 06 interval, X-ray diffraction analyses show the mineralogy to be dominated by detrital quartz, clay minerals and some feldspar, in addition to the carbonate fraction. Illite, kaolinite and chlorite have been identified as the main components of the clay fraction. Both the nature and the relative abundances of the different minerals are quite constant throughout the sampled interval. The carbonate content (Fig. 1a) shows no significant deviation from a mean value of 37 ± 2.5 wt%. Furthermore, the relative abundances of major elements (Fig. 1b) in the decarbonated fraction, determined by microprobe analysis, are also remarkably constant over the KS 06 transition zone.

The nature of the magnetic minerals was investigated by combining measurements of the IRM (isothermal remanent magnetization) acquired step-wise in fields up to 1.5 tesla (T) and of the low-field magnetic susceptibility x. The results obtained on a series of 40 samples regularly spaced over the sampled zone indicate that $90\pm4\%$ of the saturation IRM (SIRM) is acquired in a field of 0.2 T. Successive alternating-field or thermal demagnetizations show that the median destructive field of the SIRM is 25 mT and that >95% of it is lost by heating at 580 °C, complete removal being obtained between 580 and 630 °C. There are no significant differences in the low-field susceptibility of the samples, indicating that the concentration of magnetic minerals does not vary appreciably over the transition zone. Moreover, the $\chi/SIRM$ ratios are grouped around the value 4×10^{-5} m A⁻¹, typical of fine-grained magnetite ^{13,14}. All of these experiments indicate that the remanent magnetization of the clays in the KS 06 transition zone is mainly carried by magnetite, with a mineral of higher coercivity, presumably haematite, also present in very small amounts.

These magnetic minerals proved to be stable during heating. Indeed, the low-field magnetic susceptibility measured at each

step of the thermal demagnetization shows only moderate changes (up to a factor of 3) in the interval between 450 and 550 °C.

Measurements of the anistropy of magnetic susceptibility in a series of samples distributed over the transition zone show that the magnetic fabric of the sediment is characterized by an oblate ellipsoid with a very weak magnetic lineation (1.015). The axes of minimum susceptibility K_{\min} are very close to the vertical while those of maximum susceptibility K_{\max} are horizontal and their directions are largely scattered in the foliation plane. These results are a good indication of sedimentation in rather calm water; distortion of the results by bottom currents, if any, is certainly very limited.

All of the experiments carried out in the mineralogy and sedimentatology of the samples section provide evidence of a uniform, undisturbed sedimentary environment. We are well aware that this evidence does not constitute absolute proof of a constant sedimentation rate during the entire interval of sediment deposition. However, the fact that none of the measured parameters shows significant time variation makes this hypothesis very reasonable, and we can rule out the possibility of any major changes in the sedimentation rate.

Transitional palaeomagnetic directions

Measurements were made partly with a Digico spinner magnetometer and partly with a LETI cryogenic magnetometer. Both alternating-field and thermal demagnetization were used on pilot samples. The results obtained by thermal demagnetization were systematically more consistent than those obtained with the alternating field; for this reason, thermal demagnetization was used throughout, with steps of 40-50 °C from 100 °C to the highest temperature at which the measurements could still be made with sufficient accuracy.

The final palaeomagnetic directions were determined from demagnetization plots by hand-fitting a straight line through at least the last 4-5 points. Two secondary components have been identified. The first one is completely removed at $\sim 100-150$ °C.

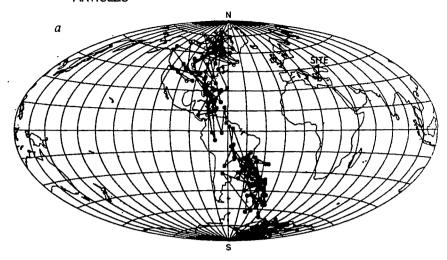

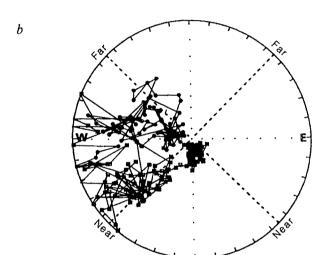

Fig. 3 a, VGP path relative to the KS 06 transition calculated from the results in Fig. 2 and plotted in the planisphere centred at 300 °E (83° west from the site longitude). b, Polar stereographic projection of the 'rotated directions' $\frac{D'}{I'}$

The second one, clearly observed in reverse- and intermediate-polarity samples, with a direction similar to that of the present geomagnetic field, is probably of viscous origin and is removed at 200-300 °C. No other unstable components have been found up to the highest temperatures, so that the final palaeomagnetic directions could be determined with a good overall accuracy (only 11 out of 245 demagnetized samples did not yield a stable direction and were rejected).

Figure 2 shows the results obtained after demagnetization, in the form of a detailed record of inclination (I) and declination (D) as a function of stratigraphic height. Each point corresponds to the result obtained on a single sample, except for 10 pairs of samples whose stratigraphic height was found to differ by less than 0.5 cm. Because this difference is less than the estimated accuracy of the measurement of the stratigraphic position, the results from these 10 pairs were averaged, and only one point is reported for each of them; the mean dispersion of the averaged directions is 11° .

The inclination values measured on samples from outside the transition zone are shallower by $\sim 10^{\circ}$ than the value of 54.5° expected at the site latitude, assuming an axial geocentric dipole field. This inclination anomaly has been frequently observed in similar sediments from throughout the Hellenic Arc¹⁵. Although no definite conclusions have been reached concerning its origin, an overall analysis of the results from many sections suggests that compaction of the sediments is a plausible cause.

The duration of the transition can be estimated by considering the stratigraphic height relative to the transitional directions and assuming a regular accumulation rate. The boundaries of the transition, defined as where the directional changes exceed the amplitude of the field variations before and after the transition, show that the stratigraphic height occupied by intermediate directions is 1.80 m. This value is twice as large as for records of the same transition in the adjacent sections Potamida 1 and 4, although the lengths of the polarity zones deduced from magnetostratigraphic results^{12,16} are the same in the three sections. We therefore conclude that the sedimentation rate during this reversal was higher than the mean value for the whole section and, moreover, that the deposition was roughly twice as fast in Skouloudhiana as in Potamida at that time. The average sedimentation rate determined by Langereis^{12,16} for western Crete is ~4 cm per 1,000 yr. Using a value twice as large for the KS 06 reversal in Skouloudhiana we obtain a duration of the reversal of ~20,000 yr. Estimates of the transition duration from directional changes^{18,19} range from 2,000 to 10,000 yr.

Discussion

Figure 3 presents the results in the alternative forms of the VGP path (Fig. 3a) and the 'rotated directions' 20 D', I' (Fig. 3b); the two representations yield very similar results. The record is characterized by a considerable number of intermediate directions—more than 120 VGP positions between 60 °S and 60° N. A very detailed record has thus been obtained and it is possible to observe some characteristics of the reversal. Some of them, previously mentioned elsewhere 11,12 , will not be discussed here, and we will concentrate mainly on the detailed variations of the transition field.

Before proceeding, it is important to examine whether the

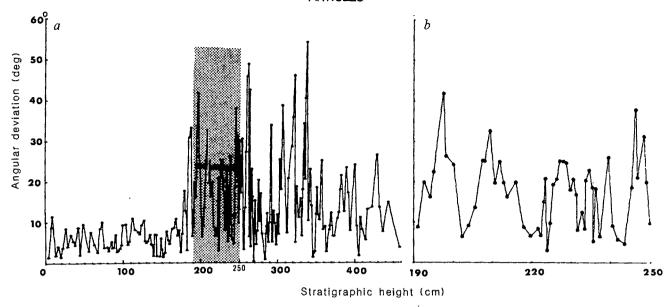

Fig. 4 a, Engular deviations between the successive magnetization vectors as a function of stratigraphic height. The shaded part of the plot is enlarged in b, to show that some of the fluctuations include several successive points.

sediment of KS 06 is adapted to this kind of study. It is well known that in a newly deposited sediment, some grains can remain free to rotate inside water-filled voids after deposition, so that a range of blocking times will be associated with each horizon within the sample, thus introducing additional spread into the magnetic record (a phenomenon known as post-detrital remanent magnetization, PDRM). Experiments using laboratory-deposited sediments^{20,21} have shown that this process depends on the type of sediment. Following preliminary work by Salloway²², the results of a model simulating the remanence acquisition in a sediment column deposited during a reversal show that a very long acquisition delay eliminates any rapid field fluctuation. Consequently, any fluctuation superimposed on a VGP trajectory is representative of a real geomagnetic field variation and a reasonable estimate of the depth of smoothing introduced by the PDRM process can be deduced from the length of the oscillations.

The results obtained on KS 06 show the presence of oscillations in the geomagnetic record, which in addition to their physical significance prove that the smoothing due to PDRM is very limited. Two types of oscillations are observed, with different time constants.

Rapid fluctuations. Fluctuations occur on a very short timescale, and a plot of the angular deviation between two successive vectors as a function of stratigraphic height (Fig. 4a) shows a significant increase of the fluctuation amplitude during the transition. Similar fluctuations are frequent in most sedimentary records of reversals and have usually been implicitly assumed to represent an overall random noise, although no thorough investigation of their origin has been performed. In the case of KS 06 several features indicate that no factor, other than the geomagnetic field itself, can account for the amplitude of the observed fluctuations.

First of all, note that several fluctuations are characterized by several successive points (Fig. 4b), and thus cannot be entirely related to random errors. The instrumental error in the measurements does not exceed 5° for the least magnetized samples, and the demagnetization diagrams are of a generally good quality. Thus, variations as large as $40-60^{\circ}$ cannot be explained by inaccuracies in the measurements or in the determination of the final palaeomagnetic directions. Fluctuations can also be induced by errors in the stratigraphic positions of the samples. However, this error is too small $(0.5 \, \text{cm})$ to account for the amplitude of the observed fluctuations. Finally, Merrill and

McElhinny²³ have pointed out that "a secondary component acquired in the relatively high fields in non-transitional times can produce a large spurious direction when vectorially added to a primary direction acquired in a relatively weak transition field". Poor magnetic cleaning could thus result in fluctuations not related to the reversal process. If this were the case, however, the vector differences between the palaeomagnetic directions of successive samples should be predominantly aligned with the direction of the dipole field at the site (or its opposite for secondary components acquired in a reverse field). A stereographic plot of these vector differences, shown in Fig. 5, shows no evidence of such a grouping, indicating that secondary components certainly play no major role in the observed fluctuations.

Thus we think that at least a significant part of these fluctuations represent very rapid variations of the geomagnetic field, and therefore there has been negligible smoothing due to PDRM. Of course, we do not rule out the effects of the previously mentioned parameters, it would not be reasonable to attribute a quantitative value to the amplitude of the fluctuations; neither do we propose a time constant, because of the averaging introduced by the stratigraphic height covered by each sample.

In their interpretation of the volcanic record of the Steens Mountain reversal, Prevot and co-workers^{3,8} suggested that the large directional jumps could reflect an increase in the level of turbulence within the Earth's liquid core during reversals. The significant increase in the amplitude of the variations observed in the KS 06 record could also reflect such an increase in turbulence.

Long-term variations. Fluctuations also occur on a considerably longer timescale, but are masked by the high-frequency fluctuations, so that a smoothing of the data was necessary to reveal them. Three independent smoothing methods have been used, involving running averages with gaussian windows, and polynomial and cubic spline approximations. The results in Fig. 6A, obtained after smoothing by cubic splines with 27 knots, are virtually identical to the results of the other smoothing procedures. The directional variations display a succession of regular oscillations, which provide additional proof that the PDRM is extremely limited.

These slow fluctuations are thus truly representative of geomagnetic changes, and therefore merit further consideration. It can be seen in the declination and inclination (Fig. 2), and in the angular variations in Fig. 6A (curve a), that three well-defined oscillations occurred before the transition, with identical

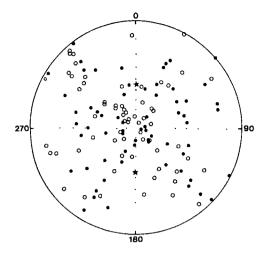

Fig. 5 Stereographic projection of the vector differences between the successive transitional directions. The normal and reverse dipole field directions at the site are represented by asterisks. Symbols, positive inclinations; open symbols, negative inclinations.

wavelengths suggesting a periodicity between 2,000 and 4,500 yr by comparison with the duration of the transition. These values are in the same range as the periodicities which are commonly reported for the non-dipolar field variations obtained from high-deposition-rate lake records during the past 15,000 yr (ref. 24). Variations with similar time constants persist during the transition, and a more quantitative picture is shown by the curve in Fig. 6B, obtained by substracting from Fig. 6Aa the monotonic angular changes of the reversal (Fig. 6Ab). The results show a very regular succession of oscillations, and the increasing amplitude of these fluctuations during the transition is consistent with the fact that the dipole field intensity decreases. Some characteristics of the non-dipolar geomagnetic field are thus not affected by the polarity change.

Reversal dynamics. The samples are almost equally spaced in stratigraphic height, and the previously described experiments have shown that there is no reason to suspect major changes in the sedimentation rate. In spite of this, it can be seen that the variations (curve b) obtained in Fig. 6A after subtracting the oscillaring part (Fig. 6b) are not strictly monotonic. This feature is also apparent from the VGP path (Fig. 3a), in which the successive positions of the VGPs are not equally distributed along the trajectory. This inhomogeneous distribution reflects the fact that the reversal did not occur at constant speed. After a quick passage of the pole through the high southern latitudes there is a quiet episode in the mid-southern latitudes, after which the equatorial zone is crossed rather quickly. It can therefore be suggested that during this reversal the least stable 'state' of the field corresponds to the middle of the transition (when the field intensity is very weak^{25,26}). Unfortunately, the number of detailed geomagnetic records is too limited (or the time sequence is too often poorly defined or interrupted) to compare the dynamical characteristics of KS 06 with other distinct reversals. It seems, however, that the VGP path configuration is similar to that associated with an R-N reversal recorded from the Chugwater Triassic formation²⁷, but differs from that reported by Liddicoat⁹ for the Gauss-Matuyama reversal from Searles Valley. There is, of course, no reason why all reversals should be characterized by the same dynamical structure.

Finally, it can be seen in Fig. 6a that the end of the record is characterized by a movement of the VGPs towards equatorial latitudes, which probably reflects a geomagnetic excursion occurring after the revesal itself. Excursions occurring before or after a transition have been observed in some records and

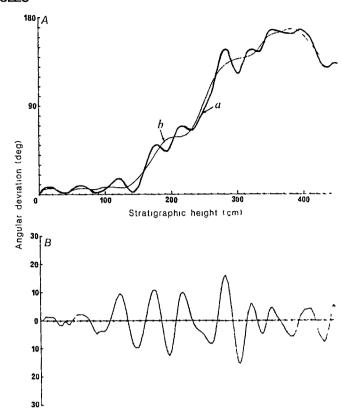

Fig. 6 A, Angular deviations from the pre-reversal direction plotted against stratigraphic height: a, after smoothing by cubic splines with 27 knots; b, after smoothing with 15 knots. B, Periodic oscillations obtained by subtracting curve b from curve a in a.

they could be related to the decrease or recovery phases of the dipole field. However, it is not always easy to distinguish, as in the case of the Steens Mountain reversal record²⁸⁻³⁰, to what extent these excursions are connected to the reversal. The configuration of transitional and excursional VGPs of KS 06 along the same longitudinal band (see Fig. 2) suggests a similarity of the mechanisms for both and, in this case, this observation can also be reconciled with Hoffman's suggestion³¹ that excursions are aborted reversals.

Conclusion

The high time-resolution of this record, which is less than a few hundred years, has allowed us to observe some detailed characteristics of the transitional field. Apart from the dynamical apsect of the reversal, which could be different for each reversal, the most important result is the presence of two types of geomagnetic field variations during the transition. Very fast fluctuations seem to be directly related to the reversal process and, as has been previously suggested², they could result from an increase of turbulence in the Earth's core during the transition. On another timescale, this record has shown the persistence of long-term variations of the non-dipole field during the transition. The non-dipole field, at least in its longer-term components (of the order of 10³ yr), has not been affected by the reversal of the main field.

This last feature has some bearing on the validity of the frozen-flux approximation. Le Mouël³² has shown that an outer-core geostrophic flow accounts for the observed temporal variations of the main field (secular variation), that is, for the different time constants of its dipolar and nondipolar parts. Indeed, this motion involves the two parts of the field in a different way and the axial dipolar component is not re-engaged in the process that builds up the secular variation. Assuming furthermore that the frozen flux approximation holds for time

spans of thousands of years, Le Mouël has demonstrated that the non-dipole field cannot disappear during the process of a geomagnetic reversal. On the other hand, Bloxham and Gubbins³³ have found evidence for flux diffusion in the South Atlantic region and have tentatively concluded that the frozenflux hypothesis can be rejected with 95% confidence. However, as pointed out by the authors themselves, this conclusion depends critically on error estimates for the field at the coremantle boundary which are difficult to assess, so that at present it cannot be considered as definitely established.

In this respect the observed continuity of the secular variation during the KS 06 reversal is to our best knowledge the first experimental evidence supporting Le Mouël's theoretical results.

Moreover, the fact that the processes leading to the observed secular variation would persist unchanged during a reversal suggests that only the internal part of the core would be involved in the mechanism of reversal.

We thank Dr C. Langereis and Dr H. Zijderveld for many helpful discussions and comments; C. Jehanno for supplying the microprobe analyses; L. De Seze for help in the mathematical treatment by cubic splines; and C. Kissel and S. Sen for help in sampling. The director of the Institute of Geology and Mining Research (IGME) at Athens kindly provided the necessary permits. This work was partly supported by the French CNRS ATP Géologie et Géophysique des Océans and CNRS-INSU ATP-Noyau, This is CFR contribution no. 761.

The gene that is abnormal in the X-linked form of the phagocytic disorder chronic granulomatous disease has been cloned without reference to a specific protein by relying on its chromosomal map position. The transcript of the gene is expressed in the phagocytic lineage of haematopoietic cells and is absent or structurally abnormal in four patients with the disorder. The nucleotide sequence of complementary DNA clones predicts a polypeptide of at least 468 amino acids with no homology to proteins described previously.

MANY inherited disorders in man result from mutations in genes whose protein products are as yet unknown. For some disorders specific proteins may be suspected as candidates for the primary gene products, whereas in other situations no biochemical clues exist. Molecular cloning offers an approach to the analysis of disease gene loci which, in principle, may be executed without specific information regarding the nature of the proteins involved. The use of genetic linkage to establish the location of a disease gene within the chromosome complement has generally been considered an initial step in this analysis1. Major diseases

of unknown aetiology such as Duchenne muscular dystrophy (DMD), Huntington's disease and cystic fibrosis, have been the focus of intensive study from this perspective²⁻⁷. It has been anticipated that extended genomic cloning⁸, coupled with searches for transcribed regions, will provide a means of defining each disease locus in precise genetic terms. Here we describe the successful application of this general strategy to the identification and characterization of the gene involved in chronic granulomatous disease (CGD), an X-chromosome-linked disorder of phagocytic cells. Affected individuals have greatly impaired host defences against infection with a wide variety of microorganisms⁹. In contrast to the normal situation, phagocytes

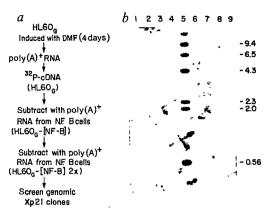

Fig. 1 Detection of a transcribed region of Xp21. a, Strategy for the preparation of an enriched cDNA probe. Granulocytic HL60 cells (HL60_G) were used as a source of mRNA and total $^{32}\text{P-cDNA}$. Sequences in common between HL60_G and the B-cell line of patient N.F. were removed by the method of Davis 32 . b, Southern blot hybridization 33 of the enriched cDNA probe with EcoRI+HindIII-digested DNAs of bacteriophage derived from Xp21. Bacteriophage clone designations: lane 1, 469-7A2; 2, 378-40A1; 3, 378-29A1; 4, 378-19A1; 6, 379A6; 7, 379 π ; 8, 55 π ; 9, 145-A1. These bacteriophage correspond to clones hybridizing with the pERT clones 469, 378, 379, 55 and 145 (ref. 15). Lane 5, HindIII-digested λ DNA as a marker. Hybridization to fragments of 2.5 and 3.3 kb was observed for the samples in lanes 6 and 7. These clones overlapped the same genomic region. Bands of greater size, visible in lane 6, are due to slightly incomplete digestion of phage 379-A6 DNA and not additional hybridizing fragments, as verified by subsequent direct analysis of the phage with cloned cDNA (not shown).

Methods. a, Total poly(A)⁺ RNA was prepared from HL60_G cells as described elsewhere^{20, 32}P-labelled cDNA was synthesized using random primers and AMV (avian myeloblastosis virus) reverse transcriptase³² (specific activity of 1 × 10⁸ c.p.m. μg⁻¹). cDNA was depleted of template RNA by base hydrolysis and hybridized in 0.5 M sodium phosphate buffer, 0.1% SDS, 5 mM EDTA in sealed glass capillaries at 69 °C to a R₀t of 2,700 with a 20-fold excess of poly(A)⁺ RNA prepared from cultured B cells of patient N.F. Single-stranded cDNA was isolated in 0.12 M sodium phosphate on hydroxyapatite at 60 °C and rehybridized to N.F. poly(A)⁺ RNA as described above³². b, Single-stranded cDNA (1× 10⁶ c.p.m.) from the second hydroxyapatite step was hybridized with the digested phage DNAs on a GeneScreen filter in a 1.0-ml solution containing 1 M NaCl, 2× Denhardt's solution, 10% dextran sulphate, 1% SDS, 0.2 M sodium phosphate, 50 μg ml⁻¹ salmon sperm DNA, 50 μg ml⁻¹ oligo(dA)₁₈ for 60 h at 68 °C. The filter was washed in 1×SSC, 1% SDS, and 0.5×SSC, 1% SDS at the same temperature. Autoradiographic exposure was for 10 days with an intensifying screen.

(granulocytes, monocytes and eosinophils) isolated from the blood of CGD patients fail to generate superoxide and activated oxygen derivatives on ingestion of microbes. The precise lesion in the membrane-associated NADPH-oxidase system of these cells is unknown. Cell complementation¹⁰ and family studies⁹ have defined X-linked and autosomal recessive varieties of the disorder. In most families the disease is transmitted as an Xlinked trait. Over the past two decades several proteins, including an unusual b-type cytochrome¹¹ and a flavoprotein¹², have been considered as potential candidates for the primary products of CGD loci, but difficulties in solubilizing membrane-associated components have impeded biochemical characterization of the oxidase system. A consistent finding in the X-linked variety, however, is the absence of the haem spectrum derived from cytochrome b^{11} . Given the potential complexity of the oxidase system and the possible requirement for assembly of several components into an enzymatically active unit, this recognized deficiency in the cytochrome b spectrum may be secondary to the primary genetic abnormality.

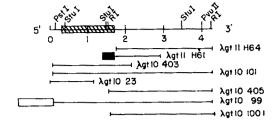

Fig. 2 cDNA clones spanning the 379-encoded RNA. Granulocytic HL60 cDNA libraries were constructed in λ gt11 and λ gt10 using procedures described elsewhere 18-20. Initial screening with a subclone from the 379-A6 bacteriophage yielded λ gt11 H64 and H61. The latter contained a segment absent from other overlapping clones (indicated by the solid box) and thought to represent intron sequences. Repeated screenings with additional cDNA subfragments of the λ gt10 library yielded cDNAs spanning the entire mRNA, representative examples of which are shown. The open box at the 5' end of clone 99 contained sequences unrelated to the 379 transcript. The cross-hatched box represents the major open reading frame of the mRNA, as defined by DNA sequence analysis (Fig. 6a).

In view of the problems inherent in conventional biochemical analysis, we have adopted a genetic approach to define the molecular basis of the X-linked form of CGD as a means of delineating at least one critical protein of the oxidase system.

General strategy

Four discrete steps are involved in our analysis: (1) The position of the CGD gene on the X chromosome (X-CGD) was mapped by both deletion and formal linkage analysis, described recently¹³. (2) Messenger RNA transcripts derived from the assigned chromosomal region were sought. (3) The relevance of one specific mRNA transcript to the disorder was investigated by studying affected patients. (4) The protein product encoded by the X-CGD gene was predicted from isolated complementary DNA clones. Taken together, the results provide persuasive genetic evidence that we have identified the X-CGD gene and characterized its mRNA transcript.

Expressed Xp21 sequences

From the study of two patients (B.B. and N.F.) with interstitial deletions of Xp21 and from linkage of X-CGD with two Xp21 DNA markers (p745 and pERT 84), the CGD locus has been assigned to Xp21.1 (refs 13-15, 42). This delimits the X-CGD locus to ~0.1% of the genome, or perhaps 3,000 kilobases (kb) of DNA. As part of chromosome walking experiments originally aimed at characterizing the DMD locus, a series of bacteriophage clones derived from seven regions of Xp21 that were absent from the DNA of patient B.B. were obtained 3.15, using pERT clones 55, 84, 87, 145, 378, 379 and 469 as probes (L.M.K. and A.P.M., unpublished data). (These bacteriophage clones span at most 10% of the DNA deleted in patient B.B.) In this manner, approximately 250 kb of Xp21 DNA was isolated

The experiment outlined in Fig. 1a was performed to search for regions of these bacteriophage clones that are transcribed in phagocytic cells. Briefly, a Southern blot filter bearing restriction enzyme-digested bacteriophage DNAs was hybridized with a radioactive cDNA probe enriched for sequences expressed in phagocytic cells. As a source likely to contain transcripts of the CGD gene, we chose cultured human HL60 leukaemic cells¹⁶ treated with dimethylformamide (DMF) for 4-7 days. Such treatment induces the NADPH-oxidase system together with most other components of granulocytic differentiation¹⁷. To remove constitutive transcripts, but not sequences derived from Xp21, HL60-cell-induced cDNA was enriched for Xp21 transcripts by subtractive hybridization twice with RNA from an Epstein-Barr virus (EBV)-transformed B-cell line of the

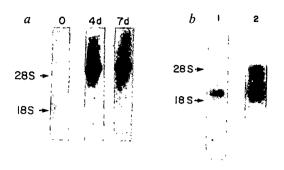

Fig. 3 Expression of 379 RNA in HL60 cells and monocytes. a, Total cell RNA (10 μ g) isolated from uninduced (0) or dimethyl sulphoxide (DMSO)-induced (either 4 days or 7 days) human leukaemic HL60 cells was analysed with a fragment of 379 cDNA derived from the 3'-untranslated region. The uninduced cells are undifferentiated HL60 cells prepared by centrifugal elutriation¹⁷. b, Poly(A)⁺ mRNA (~1 μ g) from human hepatoma cells (HepG2; lane 1) or from cultured human monocytes (lane 2) was similarly examined using the 379 probe plus phosphoglycerate kinase (PGK) cDNA. The latter detects a 2-kb mRNA species in all somatic cells³⁴.

Methods. RNA was prepared by guanidine-HCl precipitation and phenol extraction (a) or by centrifugation through CsCl₂ following solubilization with guanidine isothiocyanate³⁵ (b). Samples were electrophoresed in 1% agarose formaldehyde gels³⁶, transferred to nitrocellulose, and hybridized with a 1.8-kb Bg/II-Bg/II restriction enzyme fragment of H64 cDNA (see Fig. 5a) labelled by random priming³⁷. 28S and 18S denote the migration of ribosomal RNAs. In b, the filter was simultaneously hybridized with labelled insert prepared from the cDNA clone PGK-7e³⁴.

CGD/DMD patient N.F. (Fig. 1a). The subtracted radiolabelled cDNA, representative of \sim 500 individual mRNA sequences, was hybridized to a Southern blot of the Xp21 bacteriophage clones (Fig. 1b). Two overlapping clones, designated 379-A6 and 379- π , showed hybridization.

Isolation of cDNA clones

The results shown in Fig. 1b indicated that the bacteriophage clones originally isolated with pERT 379 contained sequences ultimately represented in the mRNA of induced HL60 cells. To locate the transcribed segment(s), non-repetitive DNA fragments of the 379-A6 insert were used as hybridization probes to Northern blots of the HL60 RNA used to generate the enriched cDNA. A probe consisting of three fragments (0.45, 0.5 and 1.8 kb) arising from a HindIII/BglII digest of a 5-kb HindIII fragment (designated 379-10) detected a 5-kb mRNA transcript (see below). cDNA clones corresponding to this mRNA species were isolated from 4-day-induced HL60 cDNA libraries constructed in bacteriophage λ gt10 and λ gt11 (refs 18-20) (Fig. 2). Repeated screening yielded cDNA clones spanning the entire mRNA transcript. Based on the frequency with which clones were obtained from the cDNA libraries, the abundance of the specific RNA in DMF-induced HL60 cells was ~0.02-0.05%. For purposes of discussion these are referred to as 379 cDNA and 379 RNA. Cloned cDNA was used to examine (1) the tissue distribution of the RNA, (2) its structure and expression in X-CGD, and (3) the nature of its predicted protein sequence.

Tissue distribution

The 379 cDNA detects a 5-kb RNA that is markedly induced in HL60 cells during granulocytic differentiation stimulated by DMF treatment (Fig. 3a). This RNA was also induced on treatment with either the tumour promoter TPA (12-O-tetradecanoyl phorbol-13-acetate) or vitamin D₃, agents that promote monocytic differentiation of HL60 cells in culture²¹. Moreover, the transcript was abundant in cultured normal human monocyte RNA (Fig. 3b) and absent from the hepatoma line HepG2

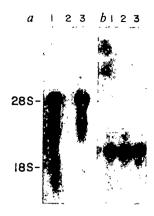

Fig. 4 Absence of 379 RNA from X-CGD monocytes. Total cell RNA (5 μ g) prepared from the cultured monocytes of two X-CGD patients (lanes 1 and 2) and from a normal individual (lane 3) was examined for 379 sequences (a) or PGK sequences (b). In addition to the patient whose sample is shown in lane 2, two unrelated patients also had monocytes that were negative for 379 RNA. Peripheral blood monocytes were isolated and cultured as described previously³⁸. Other methods were as given in Fig. 3 legend.

(Fig. 3b) as well as from total kidney, fibroblasts and HeLa cells (not shown). A low level of the transcript was detected in normal EBV-transformed B-cell lines (not shown), which have been reported to exhibit low levels of oxidase activity²².

As the RNA transcript encoded by 379 sequences appeared to be a marker for the phagocytic lineage (granulocytes and monocytes) based on our limited survey of different cell types, it represented a suitable candidate for the product of the X-CGD locus.

Relevance of 379 transcript

Given that the X-CGD locus was mapped to ~0.1% of the genome, as many as 20 transcripts derived from this region might exist in an average cell (containing perhaps 10,000-20,000 mRNA species). This estimate does not take into account possible variation in the fraction of DNA transcribed in different regions of the genome. The finding of an Xp21 phagocyte-specific RNA cannot, by itself, be interpreted as strong evidence that it encodes the X-CGD product. To determine more specifically the potential relevance of the transcript to the disease, we analysed material from classical X-linked CGD patients by hybridization with the putative X-CGD cDNA. If the transcript were derived from the relevant disease gene locus, quantitative and/or qualitative RNA or DNA alterations would be anticipated in these genetic variants.

We first analysed RNA isolated from cultured human monocytes of both normal and CGD origin. Only CGD patients with the X-linked variety were examined. Their clinical and family histories were consistent with this classification, as were negative phagocyte NBT tests9 and the absence of the cytochrome b spectrum. Figure 4 shows the monocyte RNA analysis of two such patients: in one patient (lane 2) no 379-specific RNA was detectable; in the other patient (lane 1) 379 RNA was apparently normal in size and abundance. Integrity of RNA samples was confirmed by hybridization with a constitutively expressed sequence (phosphoglycerate kinase) derived from a different X-chromosomal region (Fig. 4b). Monocyte RNA of two additional X-CGD patients examined also lacked 379specific RNA (not shown). In the RNA-negative CGD patients, Southern blot analysis with cDNA probes spanning the entire gene revealed no DNA deletions or rearrangements (not shown). These genetic variants provide strong initial support for the relevance of the 379 transcript to the disease. Although unlikely, these findings might be explained by abnormal regulation of

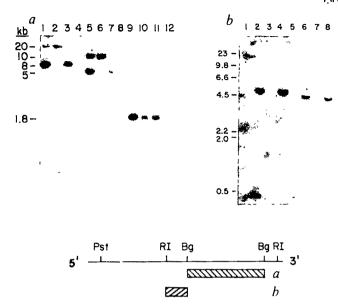

Fig. 5 Partial gene deletion in an X-CGD patient. Total cellular DNAs (5 μg per lane) were digested with BamHI (a, lanes 1-4), HindIII (a, 5-8; b, 1-4) or BgIII (a, 9-12; b, 5-8), electrophoresed, and hybridized with the regions of the 379 cDNA indicated at the bottom of the figure. a, DNAs from mother of patient J.W. (lanes 1, 5, 9), X-CGD patient J.W. (lanes 2, 6, 10) and Xp21 deletion patient N.F. ¹³ affected with CGD and DMD (lanes 4, 8, 12). Lanes 3, 7, 11, normal DNA. b, DNAs from patient J.W. (lanes 1, 5), mother of J.W. (lanes 2, 6) and patient N.F. (lanes 3, 7). Lanes 4, 8, normal DNA.

the 379 transcript due to a defect in a trans-acting factor produced by the authentic X-CGD locus.

Conclusive evidence regarding the role of the 379 transcript, though, was provided by an analysis of patient J.W. whose monocyte RNA appeared grossly normal in abundance and structure (Fig. 4a, lane 1). Analysis of DNA from patient J.W. with the 3' half of the cDNA revealed a DNA alteration on digestion with some (for example, HindIII and BamHI), but not all (for example, Bg/II), restriction enzymes (Fig. 5a, lanes 2, 6, 10). The patient's mother was heterozygous for this alteration (lanes 1, 5), consistent with her assignment as an obligate carrier. Various subregions of the full-length cDNA were used as probes to define the nature of the DNA alteration in J.W. Use of a 0.3-kb segment encompassing the middle of the cDNA revealed an interstitial deletion in the DNA (Fig. 5b, lanes 1, 5) and monocyte RNA (not shown). Most of the region between the central EcoRI and BglII restriction sites of the cDNA was absent. Sequences 3' to the deleted segment were present in both the DNA and monocyte RNA (not shown). Although the precise boundaries of the interstitial deletion have yet to be defined, it overlaps the 3' terminus of the large open reading frame (ORF) of the cDNA (see Fig. 2 and below). The failure of cDNA probes to hybridize with the DNA of the CGD/DMD patient N.F. established that the transcribed sequences were derived from Xp21 (Fig. 5a, lanes 4, 8, 12).

Thus, the 379-encoded transcript was abnormal in abundance or structure in the monocytes of all four classical X-linked CGD patients examined. These observations provide conclusive evidence that the transcript defines the product of the X-CGD locus. Therefore, we refer to it henceforth as the X-CGD RNA.

Analysis of genomic DNAs of 17 additional, independent X-CGD patients with the 3' half of the cDNA revealed no detectable DNA deletions or alterations (not shown).

Sequence of X-CGD cDNA

cDNA clones spanning the 379-encoded RNA are shown in Fig. 2. The transcriptional orientation of the mRNA was estab-

lished by hybridization of single-stranded SP6 RNA transcripts²³ to Northern blots (not shown). DNA sequences of cDNA clones were obtained from both strands either from restriction enzyme fragments subcloned into M13 vectors²⁴ or by progressive deletions as described by Dale *et al.*²⁵; the assembled sequence is shown in Fig. 6a.

Although the estimated size of the RNA transcript from Northern blot analysis is nearly 5 kb, two findings indicate that the 4.27 kb of cDNA sequence that we have obtained encompasses the entire mRNA. First, the 3' terminus is defined by clone 100.1 which contained a short oligo(dA) tract. Second, primer extension analysis revealed an extended product corresponding to the most 5' extent of clone 23 (Fig. 6b). Although we cannot exclude the presence of a strong stop for reverse transcriptase, the failure to observe cDNAs with additional 5' sequences probably indicates that the true 5' terminus of the mRNA has been recognized. Genomic studies that are in progress should assign the precise transcription initiation site(s).

A single large open reading frame, extending from potential initiator ATGs at nucleotide 208 or 322 to a termination codon (TAA) at 1,726-1,728, is present. Additional ATGs, each followed closely by an in-frame termination codon, are located at positions 35 and 113. As the ATG at position 208 is in the same translational frame as that located at position 322, we cannot unambiguously assign the initiation codon. However, given that the ATG at 322 closely resembles the consensus sequence for functional initiator codons defined by Kozak²⁶, whereas that at 208 does not, it is highly likely that the former would be used for translation initiation in vivo. Whether the upstream ATGs have a role in regulating production of the X-CGD-encoded protein is unknown.

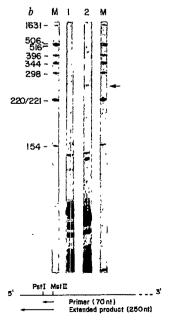

The 3'-untranslated region of the mRNA is 2.5 kb long. Although we have not analysed in detail the organization of the CGD gene in genomic DNA, comparison of the 379 bacteriophage subclones and cDNA clones indicated that the entire 3'-untranslated region is represented in a signal exon, which also contains a small coding segment 3' to the central EcoR1 site of the cDNA. A putative polyadenylation signal (ATTAAA) occurs 14 nucleotides before the poly(A) tract of clone 100.1. Several more typical potential polyadenylation signals (AATAAA)²⁷ are found elsewhere in the cDNA sequence but do not appear to be utilized in mRNA processing. A notable feature of the 3'-untranslated region is the presence of T₂₁ (nucleotides 4,018-4,028), followed 19 nucleotides in the 3' direction by TTTATT (nucleotides 4,057-4,062). On the complemetary strand this organization [AATAAA-19 nucleotides-A₂₁] resembles the 3' end of a processed transcript²⁵ ²⁹. It is possible that a processed sequence integrated at the 3' end of the CGD gene. As the genomic DNA encoding this region has the identical sequence (not shown), this novel organization in the transcript is not the result of a cloning artefact.

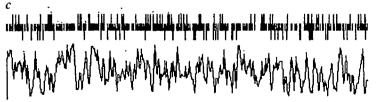

The open reading frame extending from position 322 to 1,726 predicts a primary translation product of 468 amino acids (Fig. 6) with an estimated relative molecular mass (M_r) of 54,000 (54K). If the atypical initiator ATG at position 208 were used, a polypeptide with an additional 38 amino acids at the N-terminus would result. Four potential N-linked glycosylation sites of the canonical form Asn-X-(Thr/Ser) are present. The calculated pI of the predicted protein is 9.5. Figure 6c shows the distribution of charged residues and a hydropathicity profile of the predicted protein. One extensive hydrophobic segment is evident; this spans amino acids 65-92. Screening of the GENBANK and protein database revealed no significant homology of the cDNA or of its predicted protein to known sequences.

Conclusions

Based on genetic linkage data, chromosome walking within a defined region, and hybridization with an enriched cDNA probe, we have identified and characterized the genetic locus for an

inherited human disorder (chronic granulomatous disease) without reference to a specific protein product. The derivation of the 379 RNA transcript from Xp21, its high-level expression in the phagocytic lineage, and its derangement in patients with classical X-linked CGD provide the elements of the formal argument that the appropriate locus has been recognized.

Several aspects which contributed to the success of the transcript search are relevant to its potential application to other disorders. (1) Although only ~10% of Xp21 was represented in bacteriophage clones isolated with pERT clones¹⁵, a portion of the X-CGD gene (notably its 3'-untranslated region) was fortuitously present in the collection. (2) The 3'-untranslated region of 2.5 kb provided a large, uninterrupted exon for hybridization with the enriched cDNA probe. Although almost any transcribed segments would, in principle, be detectable by hybridization of subtracted cDNA with cloned genomic DNAs. the strength of the observed signal will be greater for larger exons. (3) Previous knowledge of cells expressing the phagocytic oxidase system suggested a convenient source for the isolation of RNA used in preparation of the enriched probe. Specifically, the abundance of the 379-encoded RNA transcript in DMFtreated HL60 cells is appreciable (on the order of 0.02-0.05%). (4) The availability of an EBV-transformed cell line from patient N.F. with a deletion through the entire Xp21 region permitted removal of most constitutive transcripts from the enriched cDNA without depletion of Xp21 sequences. The extent to which our strategy may be applied to the isolation of transcripts for other disorders for which a chromosomal map position is established may well depend on these factors.

Although the oxidase system of phagocytes has been studied by conventional biochemical analyses for two decades, no clear view of the components involved or the specific protein abnormalities manifest in the major functional deficiency seen in CGD has emerged. Recently,, the findings of Segal and colleagues

Fig. 6 (Left) DNA sequence of the X-CGD cDNA (a), primer extension analysis (b) and charge distribution and hydropathicity profile of predicted X-CGD protein (c). a, Bacteriophage cDNA inserts were cloned in M13 derivatives²⁴ for sequence analysis by the methods of Sanger *et al.*³⁹ and Dale *et al.*²⁵. All regions were sequenced on both DNA strands. Clones from which sequences were derived are shown in Fig. 2. H64 and H61 were sequenced in their entirety. The initial 0.1-kb displayed was assembled from clones 23, 101, 403 and 99. The 2 kb spanning the open reading frame was derived from clone 99. Overlaps with the 5' regions of H64, H61 and 405 were examined. Based on this, and restriction mapping of genomic DNA, the intron sequences at the 5' end of H61 were identified. The extreme 3'-terminal sequences were obtained from clone 100.1. The first four ATGs in the sequence are underlined, with the predicted initiator codon double-underlined. The presumed processed cDNA sequence near the 3' end of the transcript is boxed. Canonical N-glycosylation sites are underscored with broken lines, and the presumptive poly(A) addition signal (ATTAAA) is overlined. b, The position of the 5' terminus of the X-CGD mRNA was assigned by primer extension analysis. A 70-nucleotide (nt) end-labelled primer was hybridized with yeast transfer RNA (10 µg, lane 1) or total monocyte (20 µg, lane 2) and extended with reverse transcriptase. Lanes labelled M, marker DNA. The observed product of 250 nt corresponds precisely to the 5' extent of clone 23 (see Fig. 2). Use of a synthetic 30-mer primer (nucleotides 80-110) confirmed the position of the extended product and suggested, in addition, the existence of three possible mRNA start sites within about 10 nucleotides (not shown). c, Distribution of charged residues and the hydropathicity profile of the predicted X-CGD protein. +, H and - refer to cationic (Arg, His, Lys), hydrophobic (Ala, Ile, Met, Trp, Val, Phe, Pro, Leu) and anionic (Glu, Ser, Tyr, Asp, Thr) amino acids, respectively. In the hydrophobicity profile, shown at the bottom, upward deflections indicate hydrophobic regions. Methods. b, The indicated 70-nt MstII-PstI restriction fragment was 5'-end-labelled with $[\gamma^{-32}P]$ ATP using polynucleotide kinase⁴⁰ hvbridized with RNA, and extended with AMV reverse transcriptase using methods described previously⁴¹. Reaction products were phenolextracted, ethanol-precipitated and separated in an 8% urea/acrylamide gel. Marker DNAs were pBR322 digested with Hinfl. Autoradiography was performed overnight with an intensifying screen.

have implicated an unusual b-type cytochrome in the oxidase system 11,30,31. As such, it represented a plausible candidate for the protein mutated in the X-linked form of CGD^{11,30,31}. Our results, however, argue against this conclusion. First, the aminoacid composition of the protein predicted by our sequence does not resemble that reported for purified cytochrome b^{30} . Second, the predicted protein encoded by the 379 RNA does not show significant homology to previously sequenced cytochromes of several origins. No evidence for a haem-binding region was evident from analysis of the predicted protein. Third, although its spectrum is absent in CGD granulocytes, the proposed cytochrome b protein has been reported to be present in extracts of neutrophils from affected individuals31. This finding is not in accord with the apparently frequent observation of RNA-negative X-CGD patients. Whether the predicted protein is related to the flavoprotein found in phagocytes¹² must await further biochemical characterization of the latter.

We propose that the 379-encoded protein, which we designate the X-CGD protein, is an essential component of the oxidase system of the phagocyte and probably interacts with other proteins to form an active complex. Among those components that may interact with the X-CGD protein are the membrane-associated cytochrome b and a flavoprotein. Spectral abnormalities of cytochrome b in CGD phagocytes are probably secondary to the absence (or abnormal structure) of the predicted X-CGD protein.

Characterization of the X-CGD protein in vivo and examination of proteins with which it associates should help to elucidate the organization and function of the oxidase system of the phagocyte. Analysis of the predicted sequence of the X-CGD protein has provided few clues, as yet, to the nature of the protein itself. The protein has an estimated M_r of a minimum 54K, and is probably basic. Modification at the four potential N-linked glycosylation sites may alter the apparent size of the observed protein in vivo. One marked hydrophobic region noted above (amino acids 65-92) may represent a transmembrane segment. Finally, the interstitial deletion found in patient J.W. may serve to locate an important functional domain at the carboxy-terminus of the protein, as the deletion is predicted to remove the last 50 amino acids (distal to the EcoRI site at nucleotide 1,571). Further characterization of the X-CGD protein and delineation of its functional domains will ultimately require the introduction and expression of the cDNA in phagocytic cells of X-CGD patients.

We thank Dr Temple Smith of the Dana-Farber Cancer Institute for assistance and advice in computer analysis of the sequence and Dr Mark Davis for advice on subtractive hybridization. S.H.O. is an Investigator of the Howard Hughes Medical Institute. P.E.N. was supported by NIH grant CA38325, by the Socha Memorial Fund for CGD research, and by an Established Investigatorship of the American Heart Association with funds contributed in part by its Massachusetts affiliate. This work was also supported in part by grants from the Muscular Dystrophy Association to L.M.K. and from the NIH to J.T.C. (AI-21320) and S.H.O. (HD18661).

-----LETTERS TO NATURE

A QSO with redshift 3.8 found on a UK Schmidt telescope IIIa-F prism plate

C. Hazard*†, R. G. McMahon*† & W. L. W. Sargent‡

- ‡ Palomar Observatory, California Institute of Technology, Pasadena, California 91125, USA

High-redshift QSOs (quasi-stellar objects) are important because of the information they provide on the early history and evolution of the Universe: the brighter ones are particularly valuable as probes of the intervening material. During the past 20 years much effort has been devoted to trying to discover QSOs at redshifts z > 3.5, but progress has been so slow that it has been suggested that there is a cutoff in the QSO distribution at $z \approx 3.5$ (ref. 1). However, we have already demonstrated²⁻⁴ how unfiltered UK Schmidt telescope (UKST) IIIa-F low-dispersion objective prism plates can be used successfully in such searches up to at least $z \approx 3.7$ (ref. 3). We report here the use of this technique to discover a QSO, 1208 + 1011, with a redshift z = 3.80. The highest redshift previously known was that of the radio-selected QSO, PKS2000-330 with z = 3.78 (ref. 5). In two UKST fields we have now discovered six QSOs with redshifts between 3.3 and 3.8, of which four have $z \ge 3.50$; including PKS2000-330, only four other QSOs with $z \ge 3.50$ are known over the whole sky^{5-7,10}. Our success up to z = 3.8 indicates that redshifts >4 could soon be attained.

Up to $z \approx 3.3$, searches for high-z QSOs by their Ly- α + N V emission are best carried out on IIIa-J prism plates, which have a red cutoff to their spectral response at ~5,200 Å. The IIIa-F plates, with a corresponding limit at 6,800 Å, extend the range above z = 3.3 to a possible maximum of z = 4.6. However, to avoid confusion with cool stars our searches on these plates have been restricted to the interval $3.3 \le z \le 3.9$. With this restriction and using auxiliary IIIa-D and IIIa-J prism and direct J and R or I plates to check the spectral features and colours of the IIIa-F-selected objects we have shown how high-redshift QSOs can be selected with complete reliability^{2,3}. For these prime selections we require that the reality of the emission line in the IIIa-F spectrum be confirmed by the presence of a corresponding emission line in the Ha-D spectrum and that its identification with Ly- α + N V be confirmed by the detection of O VI emission on the Illa-J spectrum. We also look for a fall in the continuum level going from red to blue across Ly- α + N v and check for, but do not demand, a cutoff near the Lyman limit. When these conditions are met, the selections are no longer candidate high-redshift QSOs but certain QSOs with redshifts within about ± 0.05 of those measured from the prism spectra; the accurate redshifts now available for our other high-z selections have allowed us to correct a slight systematic bias of +0.03 in our earlier prism redshifts. These prime selections are necessarily restricted to bright QSOs with strong O VI as well

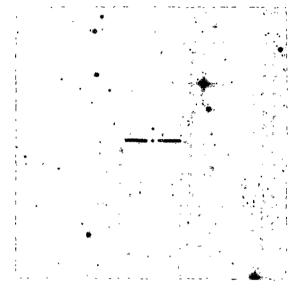

Fig. 1 Finding chart of 1208 + 1011, 8 × 8 arc min reproduced from a direct IIIa-J UKST plate (courtesy of the UKST unit). North is up, and east is to the left.

as strong Ly- α + N v emission and including 1208+1011 we have so far found only five objects²⁻⁴ which could confidently be classified as QSOs with $z \ge 3.3$ from the prism data alone; a sixth, the broad absorption line (BAL) QSO 0105-2634 with z = 3.50, appeared a certain QSO from the prism data but was relegated to the 'candidate' category because of its unusual colours⁴. As among the numerous IIIa-F selected candidates there may be high-z OSOs with weak O VI, and because we are still refining our selection criteria, we have not confined our follow-up slit spectroscopy to the certain selections. However,

Table 1 Measured wavelengths of emission lines, with corresponding redshifts

Emulsion	Feature	Wavelength* (Å)	Identification	Redshift*
IIIa-F IIa-D IIIa-J‡	Emission Emission Emission	5,860±50 ~5,950† 4,980±80	Ly-α + N v Ly-α + N v O vi	3.82 ± 0.04 ~3.89 3.82 ± 0.08
			Adopted redshift	3.82 ± 0.04

^{*} The errors are maximum errors. The calibration curve for the IIIa-F spectra was normalized using Ly- α + N v in QSOs of known redshift, assuming the wavelength of the blend to be 1,216 Å. It automatically takes into account the N v contribution unless it differs markedly from the average.

‡ The IIIa-J spectrum dispersion is perpendicular to that of the IIIa-F spectrum, and is thus not confused with the nearby star.

[†] Ly- α + N v is too close to the red limit of the IIa-D spectrum to be accurately measured. The quoted wavelength is based on measurements relative to nearby stars.

Table 2 Seven OSOs with	$\tau \ge 3.3$ visible on the 0053 -	-2803 and 1204+1129 IIIa-F prism plates

* All except the colour-selected DHM0056-2847 were discovered in the present programme.

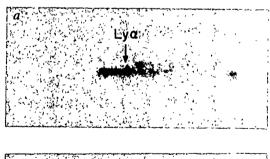

§ This is lower than the previously quoted z = 3.4, which was a provisional estimate made at the telescope.

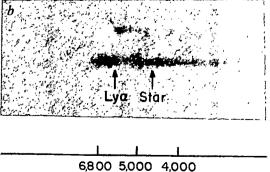

of \sim 20 'candidates' all but the BAL QSO0105 - 2634 have turned out to be galactic stars.

Until recently we possessed only one set of high-quality prism plates, centred on (RA, dec.) = $(00 \text{ h} 53 \text{ min}, -28^{\circ}03')$, and on which we found³ the z = 3.67 QSO 0055-2659. The z = 3.51OSO 1159+1223 had been found earlier² on a set of lowerquality plates, centred on (12 h 04 min, 11°29'), but it is an exceptional object with the observed equivalent width of Ly- α + N $v \approx 700$ Å. The QSO 1208+1011 was found on a new highquality IIIa-F plate of this latter region taken at an exposure of 20 min and with a limiting magnitude $m_R \approx 19$. On it, 1159 + 1223 is much more prominent than on the earlier discovery plate on which 1208+1011 is not even recognizable as a OSO. The IIIa-F spectra of both 1159 + 1223 and 1208 + 1011 from the new plate, which are reproduced in Fig. 1, with Ly- α + N v indicated in each case, show clearly the higher redshift of 1208+1011. The sharp drop in the continuum level, going from red to blue across Ly- α + N v and which is particularly prominent in 1208 + 1011, is a characteristic of high-z QSOs and in itself a valuable selection criterion. The lower visibility of the emission line in 1208+1011 shows that it has a significantly smaller observed equivalent width than the 700 Å of the emission line in 1159+ 1223. The emission line is also visible on the IIa-D spectrum, but too close to the plate's red limit to permit an accurate wavelength measurement. Its identification with Ly- α + N V was confirmed by the IIIa-J spectrum, which shows a second emission line at the expected position of Ovi. This IIIa-J spectrum, with dispersion perpendicular to that of the IIIa-F spectrum, and therefore not confused by the nearby star, also shows a highly unusual continuum distribution, with a steep decrease in level at ~4,250 Å, below which wavelength it continues faintly before disappearing at ~3,700 Å. The decrease in continuum level is ~150 Å to the blue of the Lyman limit at the emission line redshift, but relatively few QSOs show strong absorption at the Lyman limit.

Table 1 lists the measured wavelengths of the emission lines and the corresponding redshifts. The calibration curve used for the IIIa-F plate was normalized using the Ly- α + N v emission in other OSOs of known redshift. The wavelength of the Ly- α + Nv blend was assumed to be 1,216 Å, but the method of calibration automatically takes into account the N v contribution unless it differs markedly from the average. The redshifts calculated from Ly- α + N v and O vI are in such excellent agreement as to remove any doubt about the line identifications or our adopted redshift of 3.82 ± 0.04. These quoted errors are maximum errors, giving a minimum possible redshift for 1208+ 1011 of 3.78, equal to that of PKS2000 - 3305. However, a careful comparison of the IIIa-F spectrum of 1208+1011 with those of 1159+1223, DHM0054-284 and 0059-2659, all with redshifts >3.5 (refs 2, 3, 7), showed that a redshift as low as 3.78 was highly improbable. The QSO 1208+1011 was therefore selected as our highest priority object for further study, and a slit spectrum was obtained using the 5-m Hale telescope on Mount Palomar, which gives an accurate redshift of $z = 3.803 \pm 0.005$ (see ref. 8).

1208+1011 is the sixth QSO with z>3.3 to be selected from the 0053-2803 and 1204+1129 low-dispersion IIIa-F prism plates and for which slit spectra are now available. The data on all six objects are summarized in Table 2, together with those for the z = 3.61 QSO DHM0054 – 2847, which is also recognizable on the 0053-2803 plate. Their rest-frame equivalent widths, W_{λ} , of Ly- α + N v are consistent with the spread of W_{λ} in a sample of IIIa-J-selected QSOs having 2.6 < z < 3.3, with four lying towards the lower limit ($W_1 \approx 50$) of this distribution. This lower limit is not an inherent observational limit but reflects only that the preliminary surveys with both IIIa-J and IIIa-F plates concentrated on strong-emission-line objects. Other than the objects in Table 2, only eight QSOs with z>3.3 are known^{10,11}. If attention is restricted to the higher-redshift objects, the potential of the IIIa-F surveys becomes even more striking. It lists five QSOs with $z \ge 3.50$ visible in two UKST fields with a useful area of ~60 deg². There are only three other QSOs known above this redshift over the whole sky.

Wavelength (Å)

Fig. 2 IIIa-F prism spectra of the z = 3.51 QSO 1159 + 1223 (a) and of 1208 + 1011 (b) showing clearly the higher redshift (z = 3.80) of the latter object. The spectrum to the immediate right of 1208 + 1011 is that of a galactic star. (Courtesy of the UKST unit.)

[†] The magnitude of the BAL 0105 - 2636 has been corrected for heavy absorption in the R pass-band. Magnitudes are accurate to ±0.5 mag.

[‡] Calculated for $q_0 = 0.5$, $H_0 = 50 \text{ km s}^{-1} \text{ Mpc}^{-1}$ and assuming a continuum spectra index of -0.5.

The significance of 1208 + 1011 is not so much its high redshift but that it is the third QSO with z>3.3 to be found on the 1204+1129 plate. This effectively eliminates the possibility that the high density of such QSOs on the 0053 – 2802 plate³ represented only a violent statistical fluctuation or was indicative of QSO clustering. With the results from the two plates we have now established not only that QSOs with z>3.5 exist in relatively large numbers but that they may be found on unfiltered IIIa-F objective prism plates at a rate of $\sim 0.1 \text{ deg}^{-2}$ for 3.5 < z < 3.8and $m_R \le 18$. A remarkable feature is that this relatively high density is for objects with absolute magnitudes $M_R \leq -28.5$ (calculated for deceleration parameter $q_0 = 0.5$, Hubble constant $H_0 = 50 \text{ km s}^{-1} \text{ Mpc}^{-1}$ and a continuum spectral index of -0.5). At z = 2.25 similar QSOs would have apparent magnitudes $B \le$ 17.5, but the observed surface density for $B \le 17.5$ in the redshift interval 2.0 < z < 2.5 is only 0.01 deg^{-2} (ref. 12). The interval 2.0 < z < 2.5 corresponds to a co-moving volume twice that of the interval 3.5 < z < 3.8, so that, even allowing for uncertainties in the magnitude estimates, our incomplete observations imply a strong increase in the co-moving density of the brightest QSOs with increasing redshift. Our success in finding bright OSOs with z > 3.5 contrasts with the reported null detections in deep surveys over areas of 1-5 deg² for QSOs with 3.5 < z < 4.7 and $m_{\rm R} \le 21$ (refs 1, 13, 14). The results of these deep surveys appear incompatible with our observations unless the increasing density of QSOs with $M_R < -28.5$ is accompanied by a decrease in the co-moving density of lower-luminosity QSOs with $-28.5 < M_{\rm R} <$ -26, the lower limit of $M_R < -26$ corresponding to $m_R \le 21$ at z = 3.5. This implies a transition from the steep QSO luminosity function found at lower redshifts¹² to one that is relatively flat above z = 3.5 or perhaps even one where the number of QSOs per magnitude interval decreases at lower luminosities. For an unchanged flat luminosity function and constant co-moving density above z = 3.5 our observations would imply 1 QSO deg with $m_R < 21$ in the redshift range 3.5 < z < 4.7.

Above $z \approx 4.2$, Ly- α + N v will lie so close to the red limits of the low-dispersion IIIa-F prism spectra that it will be very difficult to distinguish it from the enhancement in the continuum level produced by the decreased prism dispersion which is a feature of most low-dispersion IIIa-F prism spectra and particularly those of cool stars. However, there now appears to be no problem in detecting it up to $z \approx 4.2$ because we have already seen C IV at $\lambda = 6,200 \text{ Å}$ in QSOs with $z \approx 3$. The problem in redshift range is that above $z \approx 3.9$, Ly- α passes beyond the red limit of the IIa-D emulsion and O VI moves close to the red limit of the IIIa-J emulsion so that the auxiliary plates no longer provide a useful check on the selections. Typically, our searches yield about 30 candidates per plate with 3.9 < z < 4.2. Assuming that the properties and surface density of QSOs in the redshift range do not differ significantly from those in the range 3.5 < z <3.9, we would expect only one or two of these to be genuine QSOs. About 20 candidates will need to be studied spectroscopically to give a reasonable chance of finding one QSO with z > 3.9. However, with modern instrumentation this is not a particularly formidable task, requiring about one night's observing. Also, our experience with IIIa-J prism plates has shown that the results of follow-up slit spectroscopy soon allows a refinement of the selection procedures so that the number of candidates per plate should be reduced significantly. The discovery of OSOs with z>4 would now appear to require only an adequate number of high-quality UKST prism plates and time to follow up the candidates on large telescopes. As we have already noted³, for rare objects with a flat luminosity function, the large area which can be covered by Schmidt plates in such surveys is a more significant consideration than their relatively bright limiting magnitude. Our results so far have demonstrated that these surveys can be more productive than deep surveys over small areas of sky.

We thank UKST for their help and plate material, without which our studies would not have been possible.

Hazard et al. have described the circumstances leading to the identification of a quasi-stellar object (QSO) (1208+1011) with $z = 3.82 \pm 0.04$. Here we present a moderate-resolution optical spectrum of this object. Its precise redshift, $z = 3.803 \pm 0.005$, is the highest ever recorded.

The data were obtained on 13 January 1986 UT with the double spectrograph² at the Cassegrain focus of the 5.08-m Hale telescope at Palomar Observatory. A slit of width 2 arc s was aligned along the parallactic angle corresponding to the approximate midpoint of the 4,000-s exposure. Observations were made through clouds whose extinction was visually estimated to be ~1 mag. The average air mass (density) was ~1.11. A dichroic filter directly behind the slit reflected blue light ($\lambda \le 5,500 \text{ Å}$) to one camera and transmitted red light to the other. The detector on the blue side was the '2D-Frutti' photon counting system devised by Shectman³. When used with a grating with 600 grooves mm⁻¹ and blazed at 3,780 Å in first order, this arrangement gives spectra covering the range 3,200-5,600 Å at a resolution of ~6 Å. The detector on the red side of the spectrograph was a Texas Instruments 800×800 CCD (charge-coupled device). A grating with 158 grooves mm⁻¹ blazed at 7,560 Å in first order produced a resolution of ~18 Å over the range 5,400-10,200 Å.

Calibrations were performed in the usual manner⁴, and fluxes were derived with the standard stars^{5,6} GD-248 (for the blue spectrum) and BD+26°2606 (for the red). Some uncertainty is present in the continuum shape of the QSO between ~5,100 and 5,500 Å due to the low signal-to-noise ratio in this region of the spectrum of GD-248. The two individual spectra were combined to yield one complete scan over the wavelength range 3,200-10,200 Å, as shown in Fig. 1. Although clouds affected the QSO observations, data for BD+26°2606 were obtained in similar conditions, and the absolute flux scale is probably accurate to within $\sim \pm 0.6$ mag (1σ) .

Figure 1 confirms that 1208+1011 is indeed a QSO of high redshift. Prominent, broad emission lines of Lyman- β + O VI, Ly- α + N v, Si Iv + O Iv], C Iv, and Al III + C III] are present.

^{*} Assumptions: Ly- β negligible compared to O VI; λ (O I+Si II)= 1,306 Å; $\lambda(\text{Si IV} + \text{O IV}) = 1,401.6 \text{ Å}$; Si III] 1,892 Å negligible compared to Al III 1,858 Å.

† Flux of C IV 1,549 Å = 1.77×10^{-14} erg s⁻¹ cm⁻². Galactic extinction $A_{\rm v} \approx 0.0$ mag.

‡ Observed equivalent width. Divide by 1+z=4.803 to get W in OSO rest frame.

§ Derived from z = 3.803 and the observed λ ; exact identity unknown.

|| Very approximate wavelength and redshift. ¶ Upper limit; line not detected with certainty.

Possibly contaminated by Si III] 1,892 Å and Fe II 1,860 Å.

The velocity widths of Ly- α and C IV are \sim 6,000 km s⁻¹ (full width at half-maximum) and ~18,500 km s⁻¹ (full width at zero-intensity). There is a sharp decrease in the continuum flux blueward of the Ly- α emission. This is undoubtedly due to the Ly- α absorption-line 'forest' which is so typical of distant QSOs⁷⁻⁹, and the spectrum consequently appears quite red.

Table 1 lists the observed emission lines, together with their strengths, equivalent widths, wavelengths, and redshifts. The relative intensities of strong lines are uncertain by $\sim \pm 15\%$, primarily because of difficulties in defining the continuum. Weak lines obviously have larger errors. Regions containing several closely-spaced emission lines (for example, that between Ly- α and Si IV+O IV]) exhibit a deceptively high continuum due to the blending of the line wings, so the quoted fluxes are lower limits. Extinction produced by our Galaxy is negligible at the latitude of 1208 + 1011 ($b \approx 70^{\circ}$).

A redshift of $z = 3.803 \pm 0.005$ is derived from a weighted average of the apparent peaks of CIV 1,549.1 Å, {Si IV+ O IV] 1,401.6 Å (ref. 10) and C III] 1,908.7 Å. Ly- α is not used in the average, because its blue side is eroded by numerous absorption lines. O VI is also severely affected. Although Table 1 lists several weak emission lines, they are excluded from the average because of large uncertainties in their measured wavelengths.

If redshifts are of cosmological origin, as is generally assumed, 1208+1011 is now the most distant known object in the Universe; PKS2000-330, the previous champion¹¹, has z= 3.78 ± 0.01. Like many other high-redshift QSOs, 1208 + 1011 is exceedingly luminous: we find $m(6.960 \text{ Å}) \approx 17.8$, comparable to that of PKS2000 – 330. If the Hubble constant $H_0 = 50 \text{ km s}^{-1}$ Mpc^{-1} , this corresponds to an absolute magnitude M = -30.8(for deceleration parameter $q_0 = 0$) or $M \approx -28.5$ (for $q_0 = 1$) at a rest wavelength of 1,450 Å.

With the exception of He II 1,640 Å, which is unusually weak and may even be absent, the relative strengths of emission lines in 1208+1011 are similar to those observed in many QSOs¹². Although the Ly- α /C IV ratio is slightly lower than normal, the observed flux of Ly- α is decreased by the forest of absorption lines on the blue side of the profile. High-resolution spectra are needed to quantify the effect of these lines. The C III]/C IV ratio is also fairly small, but part of the CIII] flux may have been incorrectly attributed to Al III 1,858 Å. The equivalent width (W_0) of C IV 1.549 Å in the OSO's rest frame is 22.3 Å, lower than the average value $(35\pm25 \text{ Å})$ found by Baldwin¹² in a sample of high-redshift QSOs. Given the uncertainty in the measured magnitude of 1208 + 1011, however, this W_0 (C IV) is quite consistent with the correlation he discovered¹³ between $W_0(C \text{ IV})$ and the continuum luminosity at

 $(1+z)1,450 \text{ Å}: \log L_{\text{cont}} = 33.34 - 1.57 \log W_0 \text{ (for } q_0 = 1).$ Note that a broad emission line appears to be present at a rest wavelength of ~2,080 Å. This feature has previously been seen in the spectra of some QSOs¹⁴⁻¹⁶, but its exact identity remains unknown. One possibility is permitted Fe II, as suggested by Arp¹⁵.

The continuum in the range 3,200-5,600 Å undulates in a peculiar manner. It is possible that the strong feature around 4,050 Å represents the Lyman limit of absorbing clouds at z = 3.44, but the deep, rather broad dips near 5,500 Å, 4,560 Å, and 4,410 Å are more consistent with Ly- α , Ly- β , and Ly- γ absorption (respectively) at $z \approx 3.53$. Better spectra are needed to confirm this, as well as to investigate the properties of the Ly- α forest. Unlike the case of PKS2000-330, continuum radiation is visible all the way down to the atmospheric ozone cutoff at ~3200 Å. This precludes the presence of very optically thick

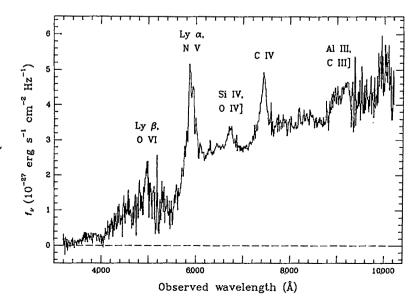

Fig. 1 Spectrum of 1208+1011, obtained with the Palomar Hale telescope on 13 January 1986 UT. A point13 convenient continuum reference $m(6,960 \text{ A})\sim 17.8$, but the flux scale is only approximate (±0.6 mag). Prominent features are marked. The blue spectrum ($\lambda \le 5,800 \text{ Å}$) is affected by numerous Ly- α absorption lines. Incomplete removal of atmospheric absorption and emission lines produces narrow spikes in some places (such as the O2 band at ~6,860 and 7,600 Å).

clouds in the range $2.5 \le z \le 3.8$ along the line of sight to 1208 +1011. At wavelength longer than ~6,000 Å, the observed continuum can roughly be described by a power law, $f_{\nu} \propto \nu^{-1}$.

We thank J. Henning, C. Price, S. Staples and D. Tennant for assistance at Palomar Observatory. This research was supported by NSF grant AST84-16704 (W.L.W.S.) and by the Miller Institute for Basic Research in Science (A.V.F.).

The rotation period of Uranus

M. D. Desch, J. E. P. Connerney & M. L. Kaiser

Laboratory for Extraterrestrial Physics, Goddard Space Flight Center, Greenbelt, Maryland 20771, USA

The recent fly-by of Uranus by the Voyager 2 spacecraft provided a singular opportunity to measure one of the fundamental but poorly known physical properties of the planet, its intrinsic rotation period. Earth-based photometric and spectroscopic estimates of the 'atmospheric' period vary greatly, with values ranging from ~12 to 24 h (refs 1-4); estimates of the period based on the dynamical flattening of a rotating body range from ~15 to 17 h (refs 5, 6). Here we use the Voyager planetary radioastronomy⁷ and magnetometer⁸ observations at Uranus to derive a period of 17.24 ± 0.01 h. The greatly improved precision of this measurement provides useful constraints on models of the planet's internal structure.

The Voyager 2 radioastronomy data provide only an indirect determination of the rotation period, because we must make the commonly accepted assumption that the periodic nature of the emission is closely related to the intrinsic rotation of the planet. In order to minimize possible measurement bias due to unknown variations in beaming of the radiation with uranographic latitude, we restricted the analysis interval to post-encounter observations, when the spacecraft latitude changed by only a few degrees. This yielded a total data span of 42 planetary rotations, from 16:00 (spacecraft time) on 25 January to 20:00 on 24 February 1986, when we observed the last detectable emission from Uranus.

This is an extremely short interval compared with the nearly 600 rotations used to determine Saturn's period9. However, the discovery⁷ by Voyager of a highly repetitive emission feature has permitted a far more precise determination than would have been possible for Saturn using an equivalent span of data. The clock-like character of this feature is apparent in total energy plots (Fig. 1), in which the radio-wave energy is derived from an integration over the frequency band from 40 to 800 kHz. The highly periodic radiation drop-outs are evident as decreases of 2-3 orders of magnitude in the total radiated power.

To obtain an initial estimate of the rotation period, the data were Fourier-analysed, following correction of the observation

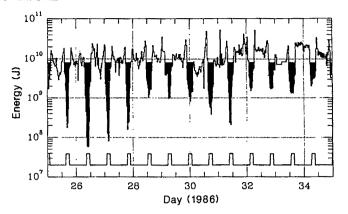

Fig. 1 Energy emitted by the Uranus radio source as a function of time for 10 days (14 rotations). For clarity, the emission dropouts are shaded. An artificial 17.24-h clock is shown as a square wave pulse in the bottom of the figure. The highly periodic nature of the emission drop-outs is evident from a comparison of the timing of the event minima with the timing of the 17.24-h clock.

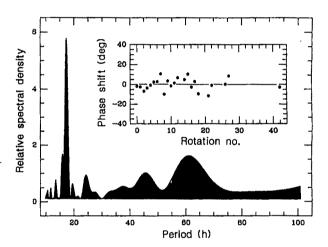

Fig. 2 Power spectral analysis of the Uranus radio-energy data of Fig. 1. The primary spectral peak is between 17.0 and 17.5 h. A linear least-squares fit to the midpoints of the emission drop-outs measured over 42 Uranus rotations is shown in the inset. When the midpoints are plotted in an arbitrary longitude system that rotates with a period of 17.24 h, the result is zero average phase shift, representing no long-term drift of the events with time. The maximum deviation of individual points from the least-squares line is ~±12°, corresponding to events leading or lagging a perfect clock by ±35 min.

times for spacecraft motion and differential light travel time. Figure 2 shows the resulting power spectral density as a function of period. There is only one significant peak in the power spectrum, corresponding to the Uranus rotation period, at $17.25 \pm 0.25 \text{ h}.$

This determination was improved by performing a linear least-squares fit to the midpoint times of the emission drop-outs. The procedure was very similar to that used to derive Saturn's rotation period⁹. By computing the phase of each midpoint in an arbitrary longitude system, the period and hence the phase shift of each point was adjusted until negligible long-term drift (zero least-squares slope) of the events with time was achieved (see Fig. 2 inset). This yielded a rotation period of 17.239 ± 0.006 h.

A second source of error in determining the period from the radioastronomy data arises from the fact that the midpoints were non-randomly distributed about the best-fit line (see Fig. 2 inset). This systematic variation introduced an additional uncer-

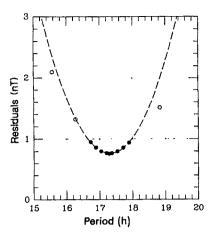

Fig. 3 Root-mean-square residual error between the best-fitting magnetic field model and the observations, as a function of assumed rotation period. The minimum r.m.s. error was obtained for a rotation period of 17.29 h. The parabolic least-squares line, shown by the dashed curve, is fit to the filled points.

tainty in the period measurement of ±0.003 h. The final determination from the radioastronomy data is, therefore, 17.239 ± 0.009 h.

The magnetic field data provide a direct measure of the rotation period of the planet's interior, where the field is generated. The data used in this study spanned the interval from 15:00 to 21:00 (spacecraft time) on 24 January 1986. During this time Voyager 2 traversed the innermost magnetosphere, passing from a radial distance of 8 $R_{\rm U}$ (the planet radius $R_{\rm U}$ = 25,600 km) at 40° S latitude, through closest approach (4.2 R_U), to a radial distance of $8 R_U$ at 78° N latitude. The maximum observed magnetic field, measured just before closest approach, was 413 nT. Without accurate knowledge of the planet's rotation period, the location of the spacecraft in the reference frame rotating with Uranus is unknown, making global magnetic field determinations difficult. In order to determine the rotation period, spherical harmonic analyses were performed with the rotation period treated as a free parameter. For each assumed period, ranging from 15.5 to 18.8 h, the best-fitting I2E1 (dipole plus quadrupole internal field plus uniform external field) model was found.

Figure 3 shows the root-mean-square (r.m.s.) residual between the best-fitting models and the observations as a function of assumed period. The best fit was obtained for a rotation period of 17.29 h, for which the r.m.s. error was 0.76 nT. We believe that this residual error is largely due to that part of the external fields (for example, fields due to the magnetopause and magnetotail currents) not well approximated by a uniform field. Figure 3 also shows a parabolic least-squares fit to the points having r.m.s. error <1 nT; the uncertainty in the parabola coefficients yields an uncertainty of $\pm 0.05 \, h$ in the rotation period.

The I2E1 model is the simplest spherical harmonic model for which an acceptable fit to the observations is obtained. Centred dipole models fit poorly (r.m.s. error >7.8 nT) for all assumed rotation periods. An offset, tilted dipole representation of the field, presented in ref. 8, has an associated r.m.s. error of 2.4 nT. More complex (for example, octupole) models can be considered only in part using generalized inverse methods¹⁰, because of the limited observations. An examination of the impact of increasing model complexity on the deduced rotation rate suggests an uncertainty several times that obtained assuming an I2E1 model, or $\sim \pm 0.2$ h. The best direct estimate of the rotation period is then $17.29 \pm 0.2 \text{ h}$.

The two period determinations made here are entirely independent and self-consistent. Combining the two periods yields a weighted mean value of $P = 17.24 \pm 0.01$ h. As no further

spacecraft observations of Uranus are planned at this time, we believe that this value is not likely to be improved upon in the foreseeable future.

The 17.24-h rotation period has important consequences for studies of atmospheric dynamics¹² and the internal structure and composition of Uranus. Inferences regarding the internal structure can be drawn from the relationship between the observed planetary oblateness, rotation period and gravitational moment (J_2) . The latter two are now known with great precision, constraining plausible models of the interior. Several 2- and 3-layer models, incorporating a 'rock' core, 'ice' mantle and gaseous outer envelope, have been considered 13,14 for Uranus. A model (U4, ref. 14) containing a rocky core of ~6.6 Earth masses (M_{\oplus}) and an outer envelope with ~3.7 M_{\ominus} H₂-H gas and 4.4 M_{\oplus} ice is most consistent with the rotation period reported here.

We thank our colleagues on the Voyager magnetometer investigation, led by principal investigator N. Ness; our colleagues on the Voyager planetary radioastronomy investigation, led by J. Warwick; and the data processing and display staff of the Laboratory for Extraterrestrial Physics, GSFC, under the direction of W. Mish, for support during the intensive Uranus encounter.

Variations in the solar ultraviolet irradiance with a period equal to or approximately one-half of the rotation period of the Sun (27 days) are currently observed by satellite monitoring. These variations have typical peak-to-peak amplitudes of ~3% between 170 and 208 nm and <1.5% at longer wavelengths. Detection of the response of stratospheric species to solar ultraviolet variability is crucial for understanding the photochemical behaviour of the middle atmosphere. Understanding the natural variations of the stratosphere is also a prerequisite for isolating possible anthropogenic effects; up to now most work has concerned stratospheric ozone¹⁻⁸. Recent analysis⁵ of measurements by the Nimbus 7 satellite's LIMS (limb infrared monitor of the stratosphere) and SBUV (solar backscatter ultraviolet) experiments has established very high correlations between ozone mixing ratios (detrended and corrected for temperature effects) and short-term variations in 205-nm solar radiation. A similar approach is used here to detect

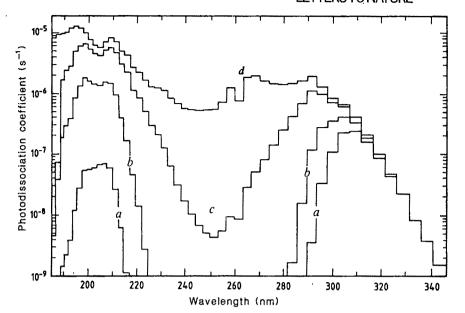

Fig. 1 Spectral distribution between 185 and 345 nm of the photodissociation coefficient of nitric acid for selected altitudes: a, 20 km; b, 30 km; c, 40 km; d, top of the atmosphere. The calculation assumes an overhead Sun (from ref. 16).

a relation between LIMS measurements of HNO₃^{9,10} and NO₂¹¹ and the SBUV measurements of short-term variations in 205-nm radiation¹². Observations show that the response of HNO₃ is much stronger than, but in the opposite sense to the ozone response, and that the NO₂ response is in the opposite sense to the HNO₃ response. This is the first detection of such a response for species other than ozone. Model calculations are in fair agreement with observed short-term variations and predict large variations in HNO₃ over the 11-vr solar cycle.

Nitrous oxide (N₂O) is the major source of odd nitrogen $(N + NO + NO_2 + NO_3 + 2N_2O_5 + HNO_3 + HO_2 + HO_2NO_2 +$ ClONO₂) in the stratosphere. It is formed in the soil by bacterial action and transported into the middle atmosphere, where it is destroyed by photodissociation or by reaction with the electronically excited oxygen atom O(1D). Nitric oxide (NO), which is produced by the reaction of N₂O with O(¹D), is converted to nitrogen dioxide (NO₂) essentially through reaction with ozone, but also by reaction with ClO, HO₂ or CH₃O₂. The NO₂ molecule reacts rapidly during the day to form NO either by reaction with O or by photolysis. During the night a significant amount of NO₂ reacts with O₃ to produce NO₃, which, in turn, is converted into N₂O₅ by reaction with NO₂. After sunrise the N₂O₅ concentration decreases continuously as solar ultraviolet radiation (primarily above 300 nm) photodissociates the molecule, replenishing NO_2 . The behaviour of NO_2 is also affected by chlorine compounds, as ClONO2 is formed by the three-body reaction of ClO and NO2. The ClONO2 is partly destroyed during the day by photodissociation or reaction with O or OH. Nitric acid is formed by the three-body reaction

$$NO_2 + OH \xrightarrow{M} HNO_3$$
 (1)

The HNO₃ molecule is relatively stable in the lower stratosphere and is therefore subject to a variety of transport processes leading, for example, to large mixing ratios at high latitudes. The loss processes for HNO₃ are

$$HNO_3 + h\nu \rightarrow OH + NO_2$$
 (2)

and

$$HNO_3 + OH \rightarrow NO_3 + H_2O \tag{3}$$

The sensitivity of HNO₃ to change in the solar ultraviolet output is predicted by a one-dimensional time-dependent chemical-radiative model^{13,14}. The short-term spectral variability⁵ of the solar irradiance is applied in the model in accord with the solar data of Heath *et al.*¹². The average solar ultraviolet irradiances adopted in the model are based on ref. 15, and we assume a sinusoidal variation of the solar ultraviolet output.

At 10 mbar, the model predicts a reduction of 0.4% in HNO₃ for a 1% increase in solar radiation at 205 nm, with a response time of less than 1 day. This strong response to short-term solar ultraviolet variations can be understood by referring to Fig. 1 (see ref. 16), in which the photodissociation frequency of HNO₃ at different altitudes is shown as a function of wavelength for overhead Sun conditions. The decrease of photodissociation with decreasing altitude for wavelengths centred on 250 nm is due to increasing ozone absorption. The sharp decrease below 200 nm is due to absorption in the molecular oxygen Schuman-Runge bands. The net effect of solar absorption by stratospheric O₃ and O₂ results in an enhancement of the effects of solar variability near 200 nm on the photodissociation of HNO₃.

The detection of the HNO₃ response to ultraviolet variations can be expected only in regions of the atmosphere where the chemical lifetime is short compared with the transport lifetime. and significantly shorter than the period of the solar oscillation. A calculation based on the model of Crutzen and Schmailzl12 shows that the chemical lifetime of HNO3 increases with decreasing altitude and, at a given level, increases with latitude, particularly in winter. At 10 mbar near equinox, for example, the HNO₃ lifetime is enhanced by 40% going from 0 to 40° latitude, while at 20 mbar it is enhanced by 60% over the same latitudinal range. In winter, the variation of the lifetime at a given altitude is larger than in other seasons. At 10 mbar, for example, the lifetime increases by more than 300% between 0 and 40° latitude. Therefore, data from near the winter solstice and high-latitude data (latitudes > 40°) were removed from the LIMS data set. Moreover, the width of the latitudinal region about the Equator from which data were used was decreased at lower altitudes ($\pm 40^{\circ}$ at 10 mbar and $\pm 20^{\circ}$ at 20 mbar), to reduce dynamical effects. By this method, the data examined were limited to those from atmospheric regions where the photochemical lifetime of HNO₃ is calculated to be less than 2 days.

Finally, to remove any possible bias, the measurements were detrended relative to a running mean, averaged over a period slightly longer than the solar oscillation period characteristic of the interval investigated (similar to the approach used for the ozone data by Keating et al.⁵). No significant HNO₃-temperature relation was predicted or observed at this level, so no correction was made. At 10 mbar, Fig. 2 shows the resulting relation between the ultraviolet ratio $(\bar{I}_{205} - \bar{I}_{205})/\bar{I}_{205}$ and the dayside HNO₃ ratio (HNO₃-HNO)/HNO₃, where I_{205} is the 5-day running mean of the 205-nm solar radiation, \bar{I}_{205} is the 19-day running mean of I_{205} , HNO₃ is the 5-day running mean of the nitric acid volume mixing ratio averaged zonally and averaged between +40° and -40° latitude, and $\bar{H}\bar{N}\bar{O}_3$ is the

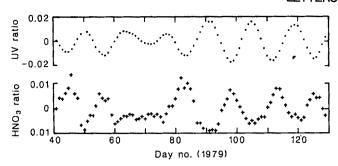

Fig. 2 Relation between dayside nitric acid ratio $[(HNO_3 - \overline{HNO_3})/\overline{HNO_3}]$ at 10 mbar (+) and 205-nm solar irradiance (UV) ratio $[(I_{205} - \overline{I}_{205})/\overline{I}_{205}]$ (\bullet) between days 40 and 130 of 1979. The correlation coefficient between the two parameters is r = -0.78.

19-day running mean of HNO3. Clearly, HNO3 is negatively correlated with the approximate 13.5-day solar ultraviolet oscillation. The correlation coefficient between the two parameters shown in Fig. 2 is -0.78. This correlation with the 205-nm solar irradiance is significantly higher than the correlation (-0.38) with the emission from the Sun at 10.7 cm (the classical 10.7-cm solar index). This is to be expected because, as indicated previously, the 205-nm radiation is very efficient in photodissociating HNO₃ throughout the stratosphere. The regression coefficient (sensitivity) for the 10-mbar dayside HNO ratio against the ultraviolet ratio is -0.44 ± 0.07 (2 σ uncertainty). In order to determine the lag time between the solar variability and the nitric acid response, the correlation coefficient between the two parameters was determined as a function of positive and negative lag (days). The resulting relationship is shown in Fig. 3: the maximum correlation occurs for a lag of 0 ± 1 days.

The 0.44% reduction in HNO₃ at 10 mbar can be compared with the variation of ozone at the same level. At low latitudes, the ozone response is calculated to be an increase of 0.17% for a 1% increase in 205-nm radiation, with a response time of 4 days (ref. 5). Observations indicate an increase in O_3 of $0.16 \pm 0.05\%$ for a 1% increase in 205-nm radiation, and a response time of 2 ± 1 days (ref. 5). Thus, the HNO₃ has an even stronger short-term response to solar ultraviolet variability than has ozone, and in the opposite sense.

It is difficult to study HNO₃ at higher altitudes because of the sharp decrease in concentration with altitude, but a similar study can be performed at 20 mbar over a smaller latitudinal interval (±20°) to minimize dynamical effects. Table 1 summarizes the results reported here and compares the model prediction (sensitivity (S) of HNO₃, expressed in per cent change, to a 1% increase in the solar 205-nm irradiance and the calculated time lag of the response) to the corresponding values derived from the LIMS data. The statistical analysis has been performed using the combined day and night data, the day data, and the night data, respectively. As the model provides 24-h averaged values, only the results provided by the combined day and night data should be compared with the calculated sensitivities. As expected, the correlation coefficient (r) is higher for the daytime observations than for the night-time. A solar effect is, nevertheless, still visible in the night data, because the signature of the daytime photochemistry is essentially frozen during the night

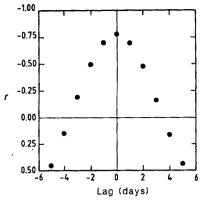

Fig. 3 Correlation coefficient between the nitric acid ratios and the 205-nm solar irradiance ratios in Fig. 2 for different time lags between these two quantities.

and is degraded principally by dynamics. The theoretical sensitivities calculated for the 13.5- and 27-day periods are in good agreement at 10 mbar with the value obtained from the data analysis, but are smaller than the observation at 20 mbar. One should, however, recall that the model provides globally-averaged sensitivities, whereas the data used for the 20 mbar analysis proceed from observations confined to the tropics, where sensitivities should be higher.

Because the photodissociation of HNO₃ leads to the formation of nitrogen oxides, there should also be a solar effect on the NO₂ mixing ratio. The LIMS NO₂ data, averaged in the same way as the HNO₃ data, show a rapid response time (less than 1 day) and positive correlation with the solar irradiance. At 10 mbar, an increase in combined day and night NO₂ of $0.22 \pm 0.12\%$ is found, for a 1% increase in the 205-nm solar irradiance. The model^{13,14} provides a corresponding increase of 0.15% in NO₂ for the 24-h average conditions. The observed NO₂ sensitivity on the dayside is larger ($+0.36 \pm 0.15\%$).

The variation in the nitric acid concentration in the stratosphere over the 11-yr solar cycle can be estimated by calculating the HNO₃/ultraviolet sensitivity from a steady-state version of the model and by scaling the amplitude of the 205-nm solar forcing to the assumed 11-yr variation. If a $10\pm5\%$ increase is adopted for the 205-nm solar irradiance (based on a number of studies, including a regression analysis between detrended 205-nm and 10.7-cm solar irradiance over a period of 4 yr), the resulting long-term variation in the HNO₃ mixing ratio is estimated to be $-10\pm5\%$ at 10 mbar and $-5\pm2\%$ at 20 mbar. The sensitivity of the HNO₃ concentration to the solar ultraviolet irradiance is thus significantly increased for this longer-period oscillation. Such a large variation may be detectable in long-term measurements of HNO₃.

The detection of a solar signal in the LIMS HNO₃ and NO₂ variations provides a new test of the validity of currently assumed photochemistry in the stratosphere. Indeed, the HNO₃ response to short-term solar variability depends on several simultaneous photochemical processes, including the sensitivity of the HNO₃ photodissociation rate to the solar radiation near 200 nm and the sensitivity of HNO₃ production to variations in NO₂ and OH. These latter parameters are modulated through O₃ and N₂O variations caused by solar ultraviolet changes. The

observed amplitude and phase of the responses at 10 mbar of HNO₃ and NO₂ to solar ultraviolet variability are in fair accord with predicted responses based on the currently accepted chemical scheme¹⁸ used in the model. The results also imply large variations of HNO3 over the 11-yr solar cycle, which should significantly affect other chemical species, including ozone. Indeed, increased solar activity can result in increased conversion of HNO3 into active NOx, which in turn can affect the ozone balance.

We thank J. M. Russell III for providing data on HNO₃, NO₂ and temperature from the Nimbus 7 LIMS experiment in November 1983, D. F. Heath for providing 205-nm solar spectral irradiance values from the Nimbus 7 SBUV experiment in August 1984, and J. E. Nealy for photochemical calculations. Some of this work was accomplished under NASA contract NAS1-15785 and CMA contract 83-468.

Novel experimental investigation of spontaneous ignition of gaseous hydrocarbons

J. F. Griffiths & W. Nimmo

Department of Physical Chemistry, The University, Leeds LS2 9JT, UK

Studies of spontaneous ignition of gases under rapid compression 1-3 are directed mainly towards understanding 'knock' in sparkignition engines and the duration of ignition delays in diesels. The relevance to engine combustion lies in the ability to investigate the effects of fuel structure on the development of spontaneous ignition (arising either in different isomers of a hydrocarbon or due to reaction of mixtures of different hydrocarbons), while avoiding complicating practical features such as droplet evaporation, induction and exhaust of the charge, reciprocating piston motion and cycle-to-cycle variations. We report here a novel development, in which a variable-speed impeller in the combustion chamber of a rapid compression apparatus is used, first, to bring about spatial uniformity of temperature and concentration throughout the ignition delay period and, second, to enhance the rate of heat dissipation by successive increases in the speed of rotation. We show that, at given conditions for rapid compression, spontaneous ignition ceases to be possible beyond a limiting rotor

The single-shot rapid compression machine⁴ is operated at a compression ratio ($V_{\text{initial}}/V_{\text{final}}$) of 10.6:1 and at a combustion chamber temperature (T_a) of 293 K. During operation the piston

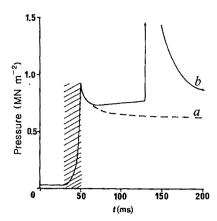

Fig. 1 Pressure-time records for non-reactive (a) and reactive (b) compositions compressed rapidly under identical conditions in the absence of mechanical stirring. Ignition occurs after a delay of 80 ms from the time when rapid piston motion ceases. The shaded area represents the interval during which rapid piston motion takes placed. The zero of time is selected by the microcomputer control system.

travels 23.2 cm from its initial position in ~22 ms and on completion of its stroke has compressed the pre-loaded (33.0 kN m pre-mixed gaseous reactants into a squat cylindrical chamber of volume 31.9 cm³ and depth 1.92 cm. End-of-compression pressures are ~0.9 MN m⁻² (~9 atm) yielding, at the moment the piston stops, gas temperatures (T_c) of 775 K in the present study. A virtually ideal adiabatic compression is achieved, and so this temperature is determined by the relationship $T_c/T_a = (V_i/V_t)^{\gamma-1} = (P_t/P_i)^{\gamma-1/\gamma}$, where γ is the ratio of the principal specific heats of the reactant mixture. Our choice of initial composition, 0.03 $nC_4H_{10}+0.20 O_2+0.77$ Ar, is governed by the desire to achieve the highest possible initial temperature, using the present mechanical system, in reactants that mimic 'typical' hydrocarbon-air mixtures in engines. Thus a stoichiometric proportion of fuel to oxygen is used, but the nitrogen is substituted by argon so as to augment γ as far as possible. The highest value for γ is that of the monatomic gases ($\gamma = 5/3$), but only in this limit is γ independent of temperature. In practice, for mixtures of gases, γ is derived at the compression temperature by an iterative procedure using a second-order polynomial representing the molar heat capacity as a function of temperature for each component of the system.

Butane, in its isomeric n- and iso-forms, is the simplest hydrocarbon with which the effect of structural change on the spontaneous ignition behaviour of hydrocarbons can be investigated. Its gaseous state is preserved throughout the course of compression. This report concerns only n-butane.

Pressure changes that take place during compression, and afterwards in the closed, constant-volume chamber, are measured by a pressure transducer and recorded digitally. Because there is no significant loss of material by leakage and because the reactant is in sufficiently great dilution that only a very small change in the number of moles of material occurs during reaction, any pressure change measured during the postcompression period reflects a temperature change. Thus, in non-reactive compositions (Fig. 1, curve a) the gas temperature (and thus pressure) falls from its maximum at the end of piston travel due to heat loss to the walls. The pressure record can be used to calculate a mean gas temperature when heat transfer occurs only by residual gas motion due to the preceding piston motion. When vigorous mechanical stirring is introduced, the measured pressure is directly proportional to the spatially uniform gas temperature. Quantitative interpretations of heat release and dissipation rates may then follow³.

Curve b in Fig. 1 is the pressure record obtained, in the absence of stirring, in a reactive composition of the same heat

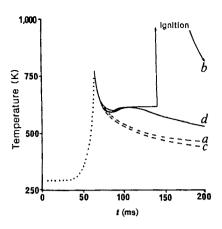

Fig. 2 Temperature-time records for non-reactive and reactive compositions following rapid compression with different rotor speeds. The dotted line represents the temperature change during the mechanical compression stroke. a, Non-reactive, stirring rate $850 \pm 50 \text{ r.p.m.}$; b, reactive, stirring rate $850 \pm 50 \text{ r.p.m.}$; c, nonreactive, stirring rate 1,100 ± 50 r.p.m.; d, reactive, stirring rate $1,100 \pm 50 \text{ r.p.m.}$

capacity as that associated with curve a. When piston motion ceases, the two curves at first show an identical cooling rate: the initial rate exceeds 3×10^4 K s⁻¹. The separation of curve b from curve a at 10 ms after compression shows that heat is being released from the exothermic oxidation of butane at a sufficient rate to augment the gas temperature. The mean temperature corresponds to 610 K at this time. During the next 70 ms the temperature increases monotonically (by ~50 K): thermal feedback is taking place. There is a critical transition to ignition 80 ms after rapid piston motion ceases, due not only to the enhanced reaction rate caused by the rising temperature but also to chain branching by means of organic peroxides formed as molecular intermediates during the ignition delay period⁵. Photographic records of the development of ignition in the chamber have been published elsewhere⁶.

Figure 2 shows temperature-time records derived from pressure histories obtained under the effect of mechanical stirring. The dashed curves (Fig. 2a, c) are from the cooling of a nonreactive composition when the rotor speed is raised from 850 (±50) to 1,100 (±50) revolutions per minute. An enhanced cooling rate is discerned after 10 ms into the post-compression period, once the initially dominant gas movement caused by rapid piston motion has subsided sufficiently. The corresponding records from reactive compositions at the respective rotor speeds are shown as solid curves (Fig. 2b, d). There is a failure of spontaneous ignition at the higher rotor speed (curve d) even though exothermic oxidation has taken place. Ignition has failed in this case because the heat release rate, which rises to a maximum and then begins to wane as the primary reactant concentration falls, is unable to maintain the gas temperature. The heat release rate diminishes to zero at 80 ms after compression (W.N., unpublished data). At marginally supercritical conditions (curve b), the heat release also falls virtually to zero just before hot ignition takes place, but as a consequence of the lower heat dissipation rate, the reactant temperature remains higher and chain branching becomes effective, giving rise to chain-thermal criticality⁷.

Climatic change and Aboriginal burning in north-east Australia during the last two glacial/interglacial cycles

A. P. Kershaw

Department of Geography, Monash University, Clayton, Victoria. Australia 3168

Long palynological records from continental deposits may be divided into two categories: detailed sequences seldom extending back much further than the most recent interglacial 1-3, and more generalized or discontinuous sequences which cover all or a substantial part of the Quaternary⁴⁻⁶. I present here a record which is unusual in that it provides, in some detail, changes through a period considered to embrace the last two glacial/interglacial cycles. It provides the opportunity to compare the results of climatically-induced changes at corresponding stages within the two cycles and also to assess the impact of Aboriginal people on the vegetation. People have been present in Australia for the past 40,090 years⁷ and possibly as long ago as the last interglacial period⁸, but are unlikely to have been present before this.

The record presented here is an extension of that described previously from Lynch's Crater on the Atherton Tableland⁹⁻¹². Figure 1 shows selected results, including percentages of major gymnosperm and angiosperm big-tree taxa derived from rainforest, and the most common canopy tree taxa from open sclerophyll vegetation, together with a summary of the relative proportions of all pollen from these three groups. Six major zones are recognized, of which the top four have been described previously¹¹. Zones G, E and A are dominated by pollen from rain-forest angiosperms, zones F and D contain high percentages of the rain-forest gymnosperms Araucaria and Podocarpus together with a substantial sclerophyll component, and zone B is dominated by the sclerophyll taxa. Zone C is transitional between rain-forest and sclerophyll-dominated periods. A timescale has been determined for the past 40,000 yr from radiocarbon dates and estimated beyond this time by applying known rates of accumulation of similar sediments from sites within the region to sections of the core, taking into account the degree of sediment compaction¹³.

A large degree of vegetation variation can be explained as a response to climatic change, particularly precipitation. Very high values for rain-forest angiosperms in zones G, E and A indicate domination by complex rain-forest existing in high rainfall conditions. Slightly higher gymnosperm values and higher percentages of Elaeocarpus relative to Cunoniaceae in subzone E1 than in zone A and subzones G2 and E3 suggest that precipitation did not reach equivalent levels, while generally higher sclerophyll and rain-forest gymnosperm percentages in subzones G1 and E2 indicate that effective precipitation was lower still.

Sharp reductions in precipitation are suggested at the beginning of zones F and D by substantial rises in sclerophyll taxa, particularly Casuarina, and the gymnosperm Araucaria. Subzone D2 can be separated on the basis of a higher rain-forest angiosperm component and a peak in Elaeocarpus, which signify slightly wetter conditions. The increases in sclerophyll taxa through zone C and their predominance in zone B are difficult to interpret in climatic terms, but precipitation was certainly no higher than in the period represented by zone D.

The best-estimate precipitation curve in Fig. 1 is based on information derived from modern pollen samples10 and on the known ecology of individual plant taxa and vegetation types. A more cautious precipitation estimate is shown as a range calculated mainly from bioclimatic analyses¹⁴ undertaken on an extensive Australian rain-forest data set15. The range is one standard deviation from the mean annual precipitation calculated for the most likely predominant structural vegetation type 16

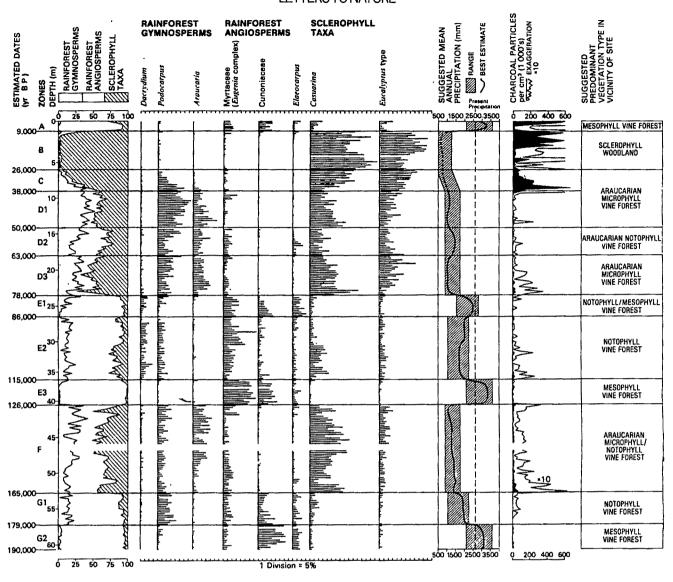

Fig. 1 Selected attributes of pollen diagram from Lynch's Crater. The frequencies of pollen of all taxa are shown as percentages of the dry-land-plant pollen total.

surrounding the pollen site during the period represented by each zone.

A comparison of the precipitation curve with that from the deep-sea core V28-238¹⁷ (Fig. 2) reinforces the suggestion from analyses of the more recent part of the record that precipitation changes within this area have been largely controlled by global changes in sea level and/or sea surface temperatures¹⁸.

Despite the strong climatic control of vegetation variation, there are some features of the record which cannot be explained by climate alone. One example is the inconsistent performance of Eugenia complex, particularly within the high-precipitation 'interglacial' periods represented by zones G2, E3 and A. This is at least partly related to the inclusion in the taxon of several different species with various ecological requirements and differential pollen production and dispersal capabilities. This is a common problem of palynology in areas dominated by highly diverse communities. A second feature is the attainment of somewhat different percentages by taxa and taxon groups in corresponding phases of the two identified cycles. This applies most obviously to the attainment of higher levels of gymnosperms within the penultimate glacial. The preferred explanation here relates to the general infilling of the lake basin and its effects on pollen influx. With the extension of swamp over the lake basin, it is probable that the inwash pollen component, likely to have been dominated by lake-edge angiosperms with poor aerial pollen dispersal, would have been reduced. This would have effectively increased the proportions of wind-dispersed, more regional pollen such as that from the gymnosperms.

The most important difference between the two cycles is the almost total replacement of rain-forest by sclerophyll vegetation towards the end of the most recent dry period. It was originally proposed that a change in climate could not alone have brought about this change because of the potential of 'drier' rain-forest to survive mean annual precipitation levels as low as 600 mm on basaltic soils such as those surrounding the site, and because of the extinction of *Dacrydium* and perhaps other taxa which must have been equipped to survive the vicissitudes of Quaternary climates^{9,10}. Instead, an increase in burning, most probably due to the activities of Aboriginal people, was proposed as the most likely cause. Subsequently, charcoal analyses on the core sediment indicating a sharp increase in burning about 38,000 yr ago (see Fig. 1) gave some support to this interpretation⁸.

The evidence presented here, that sclerophyll vegetation did not totally replace rain-forest during the penultimate 'dry glacial' period in contrast to the last 'glacial', is strong support for a

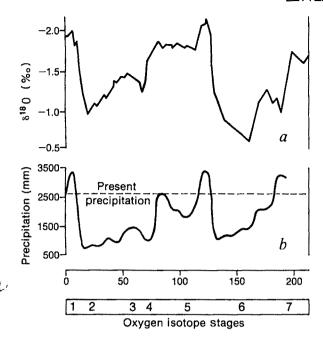

Fig. 2 Comparison of the precipitation curve derived from Lynch's Crater (b) with the oxygen isotope curve from deep-sea core V28-238 (a). Oxygen isotope stages from ref. 17.

recent increase in burning. Furthermore, the nature of the change from araucarian vine forest to sclerophyll vegetation can be shown to be different from other major changes in the record for which a climatic cause is invoked. Most changes from one zone to another are abrupt, and span perhaps only a few hundred years. Small charcoal peaks accompanying many of these changes suggest a role for fire in facilitating the climatically controlled transition from one vegetation state to another, as has been proposed for vegetation changes elsewhere 19-21. By contrast, the change to sclerophyll vegetation is gradual, taking as long as the period represented by zone C, perhaps ~12,000 yr. It is best explained as a gradual replacement of fire-sensitive rain-forest by fire-promoting sclerophylls under a regime of frequent burning of the sclerophyll vegetation.

Application of laser holographic techniques to investigate crustal deformations

Shuzo Takemoto

Disaster Prevention Research Institute, Kyoto University, Kyoto, 611 Japan

Laser holographic techniques can be used to detect small deformations of three-dimensional objects, of the order of the wavelength of the laser light. We report the use of laser holography to measure the crustal deformation in a deep tunnel at Amagase, Kyoto, Japan. A recording system consisting of a helium-neon gas laser and associated optical elements was installed in the observation tunnel in 1984. Using this sytem, holograms of a section of the tunnel wall ~2 m in diameter are directly recorded on photographic plates. When the reconstructed image of a hologram is superposed on the current ('real-time') image of the tunnel wall, many interference fringes can be seen through the developed photographic plate. The fringe displacement, formed by the deformation of the tunnel, is continuously monitored with a video camera and a video-cassette recorder. The measured fringe displacement in the interference pattern is consistent with strain changes obtained from extensometers which have been installed in the same tunnel.

Observations of crustal deformation have been commonly made with extensometers by continuously measuring the relative displacement between two piers fixed into the bedrock. The

early developments of these instruments were due to Benioff¹, Ozawa² and Takada³. Their extensometers, using length standards of fused quartz tubes or super-invar bars, have been installed in many observatories for investigating secular strains, tidal strains and low-frequency seismic waves. Extensometers of this type, however, suffer from the disadvantages inherent in length standards of solid material, that is, deformation of the length standards themselves and frictional forces between length standards and their supports. In contrast, laser extensometers are free from these disadvantages because they are capable of detecting linear strains without using length standards of solid material. Various instruments have been developed by a number of groups in the past two decades⁴⁻¹¹. In addition, unlike conventional extensometric methods, which can detect only onedimensional linear strains, the holographic method can detect two- or three-dimensional strain patterns.

Laser holography has been used to measure tunnel deformation at the Amagase Crustal Movement Observatory since 1984. A laser holographic recording system was installed 320 m from the entrance of a disused tunnel of length 1,830 m. The section of the tunnel has a horseshoe shape, with a diameter of ~ 6 m. The observation site is ~ 130 m below the surface. The annual variation of air temperature at the observation site is ~ 0.2 °C

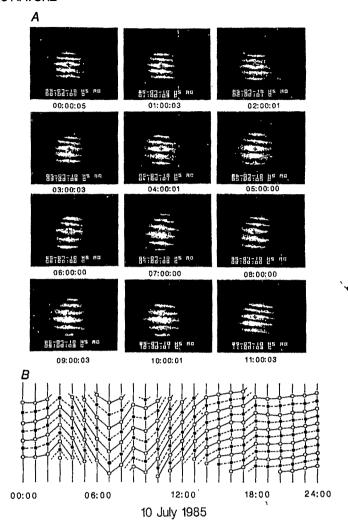

Fig. 3 A, Examples from 10 July 1985 of interference fringes superposed on the holographic image of the tunnel wall, on which the standard mark '+', has been drawn with black paint. B, Hourly plots of fringe displacements measured along the vertical line (~1 m) passing through the standard mark '+'. Open and filled circles represent bright and dark fringes, respectively. The plots are inverted (upside-down), for convenince of comparison with Fig. 4.

and its daily variation is <0.05 °C. The amplitude of microtremor measured in the tunnel does not exceed 20 nm s⁻¹ at \sim 0.1-10 Hz. These quiet circumstances allow us to obtain clear holograms of objects having a dimension of \sim 1 m. Figure 1 shows the arrangement of the holographic recording system together with three laser extensometers (L-1, L-2, LS-1) which have been installed in the same tunnel.

The holographic recording system consists of a helium-neon gas laser with an emission power of 50 mW, optical mirrors and lenses, a video camera and a video-cassette recorder. Optical elements, with the exception of a reference mirror, are fixed with magnetic holders to a massive steel plate (60 × 90 cm) which is fastened to a concrete base on the floor. The reference mirror ('M' in Fig. 1c) is attached to the tunnel wall with anchor bolts. The laser source is set on another concrete base and covered by polystyrene boards. A coherent light beam emitted from the laser source is split into two beams at the surface of the beam splitter, which deflects ~5% of the light beam and transmits the remaining portion. The former is used as a reference wave and the latter illuminates an area of the tunnel wall ~2 m in diameter. Two waves, reflected from the reference mirror and the tunnel wall, respectively, are superposed on a photographic plate (Agfa 10E75) measuring 6.5×9 cm. After an exposure of

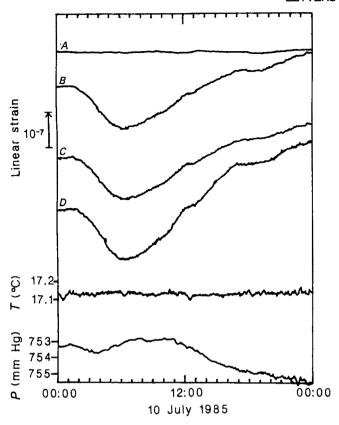

Fig. 4 Strain changes observed with laser extensometers installed in the Amagase tunnel [A, (L-1); B, (L-2); C, ((L-2)-(L-1)); D, (LS-1)], together with thermometric and barometric records on 10 July 1985.

~1-3 min, the photographic plate is developed and fixed. The developed plate is used as the original hologram, and is carefully reset in the position at which the hologram was taken. By again illuminating the plate with the same reference wave, the holographic image of the tunnel wall is reconstructed. In this procedure, the plate is slightly inclined from the original position. A number of dark and bright lines ('fringes') over the object image can then be seen on the hologram: these are caused by the interference of two waves; one reconstructed from the hologram and the other scattered directly by the tunnel wall. The movements of these interference fringes enable us to estimate the tunnel deformation.

We now calculate strain changes in a long tunnel which is assumed to be driven in an infinite, homogeneous, isotropic, elastic medium. Because the change in strain components along the tunnel axis can be assumed to be negligibly small compared with that across the tunnel, calculations are made with the two-dimensional finite element technique under the plane-strain condition. Results of the calculations are illustrated in Fig. 2B-D. Figure 2B shows displacements around the tunnel due to the uniaxial tensile stress which would produce uniform strains (Fig. 2A) in the absence of the tunnel; Fig. 2C and D show displacements of the tunnel wall relative to the points 'O' and 'M', respectively. Fringe displacements in the interference pattern at the Amagase tunnel are predicted from these figures. If the developed photographic plate is adjusted to produce interference fringes parallel to the direction of tunnel axis, upward and downward displacements of fringes and changes in their width should be observed: the former correspond to the mean displacement of the tunnel wall relative to point O and the latter correspond to the tilt of the tunnel wall relative to point M.

Figure 3 shows examples of fringe patterns recorded with the video-cassette recorder, together with hourly plots of their position on 10 July 1985. The drift of the fringe indicates an initial

upward trend, reversing at 03:00 and again at 07:00. The fringe width is narrowest at 03:00 and widest at 07:00.

The holographic results may be compared with the strain changes measured by laser extensometers.

Figure 4A and B are the linear strains measured by laser extensometers L-1 and L-2, with a frequency-stabilized laser source and mutually perpendicular evacuated light paths. As shown in Fig. 1B, L-1 is oriented along the tunnel and L-2 across the tunnel. The curve in Fig. 4C shows the difference between these two components of linear strain ((L-2)-(L-1)). The curve in Fig. 4D shows the strain measured by a new type of laser extensometer¹⁰ which has a simple, unstabilized laser source and two light paths of equal length, and detects the difference between two axial linear strains. (LS-1) is thus equivalent to (L-2) – (L-1). The strain change along the tunnel (L-1) is smaller by an order of magnitude than that across the tunnel, (L-2): this is explained by the cavity effect¹². Therefore, (L-2) - (L-1) and (LS-1) are nearly equal to (L-2), which has a maximum at 02:00 and a minimum at 07:00 on 10 July.

The trends of the strain changes observed with extensometers are consistent with those of the fringe displacements in the interference pattern shown in Fig. 3B. Thus, the fringe displacements observed with the laser holographic method are indicative of the tunnel deformation caused by tectonic and tidal stresses. In addition, the change of the fringe width is probably related to the tilt of the tunnel wall. This method is likely to prove useful in the observation of crustal deformation.

I thank Drs Torao Tanaka, Yoshimasa Kobayashi and Kojiro Irikura for critical reading of the manuscript.

The Banda-Celebes-Sulu basin: a trapped piece of Cretaceous—Eocene oceanic crust?

Chao-Shing Lee* & Robert McCabe

Geodynamics Research Program and Department of Geophyics, Texas A&M University, College Station, Texas 77843, USA * Present address: Bureau of Mineral Resources, Geology and Geophysics, Canberra ACT 2601, Australia

The Banda, Celebes and Sulu basins are poorly understood marginal seas located at the junction of the Eurasian, Indian-Australian and Pacific-Philippine Sea plates. The incompleteness of the data sets, the complex geology of the surrounding islands and the late Cenozoic evolution involving subduction, rifting, transform faulting and island arc collision have complicated tectonic interpretation of the region. The Banda basin is underlain by oceanic crust¹⁻³. Bowin et al.² and Lapouille et al.³ have suggested that it is a trapped oceanic basin which was once continuous with the late Jurassic Argo Abyssal Plain off north-west Australia. Similarly, the Celebes and Sulu basins are also underlain by oceanic crust⁴⁻⁶. On the basis of newly identified magnetic reversal ages (Fig. 1), heat-flow data and on-land geological studies, we

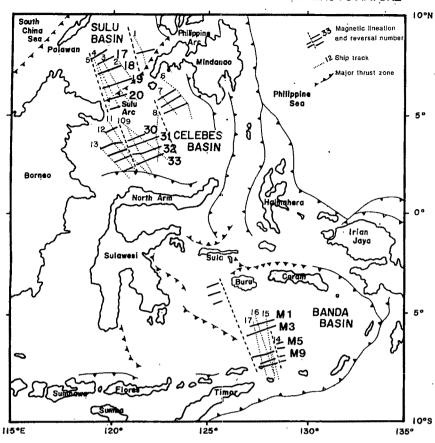

Fig. 1 Tectonic structure and magnetic anomalies in the Banda, Celebes and Sulu basins. Dotted lines are the ship tracks used for magnetic correlation in Figs 2-4. (The timescale used in this and succeeding figures is from refs 7 and 8.) These data are compiled from the global marine geophysical data set. The data sources are the Lamont-Doherty Geological Observatory (profiles 2, 4-6, 9-14 and 16), the Scripps Institute of Oceanography (1, 3, 7, 8 and 15) and the Woods Hole Oceanographic Institution (17). The tectonic structures are revised from Hamilton 16.

suggest that the Celebes and Sulu seas may have been continuous with the Banda basin. This Cretaceous-Eocene basin has been dissected into its present configuration by Tertiary tectonic processes

Re-analyses of the existing marine geophysical data suggest that the magnetic lineations in the Banda, Celebes and Sulu basins have similar trends, of about N70 °E, N60 °E and N55 °E, respectively. Although the incomplete data sets from each individual basin do not allow magnetic ages to be determined confidently, we believe that a combined analysis of the magnetic anomalies from all three basins does permit a tentative best fit to the geomagnetic reversal model^{7,8}. Our assignments are: (1) anomalies M1-M11 (111-123 Myr BP) in the Banda basin at a half-spreading rate of \sim 2.9 cm yr⁻¹; (2) anomalies 30-33 (65-72 Myr) in the Celebes basin at a half-spreading rate of ~3.9 cm yr⁻¹; and (3) anomalies 17-20 (41-47 Myr) in the Sulu basin at 4.2 cm yr⁻¹ (Figs 2-4). The magnetic anomalies in each of these three basins become younger toward the north. Similar north-east-trending late Jurassic anomalies have also been identified in the Argo Abyssal Plain⁹. These observations suggest that the Banda-Celebes-Sulu ocean basins were once part of a continuous basin, probably a northern extension of the eastern Indian Ocean¹⁰

Recent seismic reflection and side-scan sonar studies in the Banda Sea^{11,12} have shown that the central portion of this basin is composed of prominent north-east-trending ridges and faults. Dredge data, collected in coordination with these geophysical studies, suggest that these ridges represent slivers of a continental margin. The presence of these structural features in the central portion of the Banda Sea suggests that the basin may have a complex tectonic history and is presently dissected into two or more smaller basins. This complication aside, both our model and that of Lapouille et al.³ for the Banda basin suggest that the entire basin is early Cretaceous in age and becomes progressively younger to the north.

Heat-flow data from the three basins are qualitatively consistent with our assigned magnetic ages: the averaged heat-flow

data fit the Parsons and Sclater¹³ heat flow versus age curve for an oceanic basin. Thus, the Banda basin² is characterized by low heat-flow values, averaging 1.09 h.f.u. (1 h.f.u. = 1 μ cal cm⁻² s⁻¹ = 41.87 mW m⁻²), the Celebes basin^{6,14} by intermediate heat flow, averaging 1.38 h.f.u., and the Sulu basin¹⁴ by high heat flow; averaging 1.67 h.f.u. The fact that the heat-flow data show a good fit to the Parsons and Sclater curve also suggests that these basins are probably underlain by normal oceanic crust. (Heat flow in back-arc basins does not usually fit the global heat flow versus age curve¹⁵ this well.) The bathymetric data from the three basins also show a crude age-dependence, the Banda basin being the deepest and the basins to the north becoming progressively shallower.

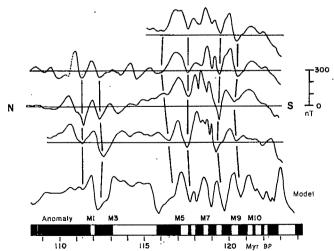

Fig. 2 Correlations of magnetic profiles with the geomagnetic timescale in the Banda basin. (The timescale used in this and succeeding figures is from refs 7 and 8.) The model is a phase-shifted synthetic magnetic profile with $\theta = -15^{\circ}$ where θ is the phase shift angle (see Schouten and McCamy³⁰).

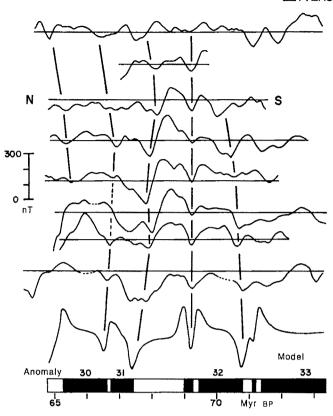

Fig. 3 Correlation of magnetic profiles with the phase-shifted synthetic model ($\theta = -330^{\circ}$) in the Celebes basin.

The region is complicated by numerous landmasses that divide this old oceanic basin into the present configuration of marginal seas (Fig. 1). We argue that each of these landmasses either arrived at its present location by late Tertiary tectonic movements or has been constructed in place upon this older oceanic basement. Below we briefly discuss the origin of these landmasses.

The Philippine Arc, a complex mixture of early Cretaceous to Recent island arc fragments and ophiolites¹⁶⁻¹⁹, appears to have been welded together in early to middle Tertiary time. Palaeomagnetic studies^{20,21} in the central Philippines show that this island arc has undergone motions that are consistent with the clockwise rotation of the Philippine Sea plate²². This suggests that the Philippines were located far to the south-east during the middle Tertiary. Northern Palawan is a microcontinent, composed of Palaeozoic rocks, which rifted away from southern China and translated southward during the Oligocene to Miocene opening of the South China Sea^{16,23,24}. The limited data for the Sulu Arc suggest that these islands are a late Neogene volcanic arc which developed in response to the southward subduction of the Sulu Basin¹⁶. Although the age of the island arc ophiolite is unknown, radiolarian cherts from eastern Borneo yield a late Cretaceous to Eocene age²⁵. This age is consistent with the suggestion that the basement is composed of pieces of the hypothesized Banda-Celebes-Sulu ocean basin.

Eastern Sulawesi is characterized by an ophiolite and mélange belt faulted against a metamorphosed sequence of marine strata¹⁶. Western Sulawesi, including the east-west-trending North Arm, is composed of folded sequences of Mesozoic and Tertiary metamorphic rocks, Cenozoic platform deposits and arc-derived volcanic and sedimentary rocks²⁶. Western Sulawesi probably rifted away from eastern Borneo during the middle Tertiary¹⁶. It has been suggested that the Neogene arc of the North Arm, a north-facing arc system, results from a change in subduction polarity and a clockwise rotation of the active arc16,27. Although Sulawesi now divides the Celebes and Banda

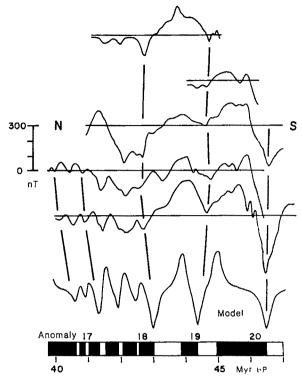

Fig. 4 Correlation of magnetic profiles with the phase-shifted synthetic model ($\theta = -270^{\circ}$) in the Sulu basin.

basins, we suggest that the separation of these two basins occurred during the Tertiary.

The islands of the north Banda basin, including Sula, Buru and Ceram, are composed of mélanges and continental rocks16. Stratigraphic models indicate that these islands were rifted continental fragments detached from Irian Jaya in the late Cenozoic and transported westward by strike-slip faulting28. Most of the south Banda basin islands are Neogene volcanic features developed in response to late Tertiary subduction around the Banda basin¹⁶. Timor is believed to be made up of portions of the foundered Australian crust incorporated into the upper plate during the Cenozoic 16,29. Before this Neogene tectonics, our model suggests that this ocean and Australia were part of the same plate.

Based on marine geophysical data we propose that the Banda, Celebes and Sulu basins formed a continuous ocean basin during Cretaceous to early Tertiary times. This hypothesis is supported by the fact that the various islands which currently fragment this older basin either arrived at their present location by middle to late Tertiary tectonic movements or were built in place by Neogene subduction. The trapped portions of old oceanic crust were further reduced in size by Neogene subduction beneath the Banda Arc, the North Arm of Sulawesi and the Sulu archinelago.

We thank Tom Hilde, Robin Lighty, Jay Cole and Chris Pigram for their comments and reviews. The research was supported by the United States Department of Energy, the Center of Energy and Mineral Resources at Texas A&M University and the Amoco Production Company. This is Texas A&M Geodynamics Program Contribution No. 49.

Seismic measurements reveal a saturated porous layer beneath an active Antarctic ice stream

D. D. Blankenship, C. R. Bentley, S. T. Rooney & R. B. Alley

Geophysical and Polar Research Center, University of Wisconsin-Madison, 1215 West Dayton Street, Madison, Wisconsin 53706, USA

Seismic reflection studies recently conducted on ice stream B, part of the marine ice sheet of West Antarctica, show a metres-thick layer immediately beneath the ice in which both compressional (P) and shear (S) wave speeds are very low. These low wave speeds imply that the material in the layer is highly porous and is saturated with water at a high pore pressure. From this, and from arguments presented in an accompanying paper to the effect that the layer would be too weak to support the shear stress exerted by the overlying ice, we conclude that the layer is deforming and that the ice stream probably moves principally by such deformation.

For the past decade, the stability of marine ice sheets (ice sheets grounded below sea level) has stood as a fundamental unsolved problem in glaciology. In particular, the West Antarctic ice sheet has been of concern because of the possibility that it might shrink rapidly in response to climatic warming, thus raising sea level by ~5 m. But no understanding of the dynamics of the West Antarctic ice sheet is possible until the processes and interactions that govern the development and movement of ice streams, by far the most active parts of the ice sheet, are understood.

Consequently, a major program was initiated in 1983 to study the West Antarctic ice streams that feed into the Ross Ice Shelf and their interaction with that ice shelf. One aspect of this program is a concentrated geophysical study at a site on ice stream B (Fig. 1), aimed at learning more about the nature of the contact zone between the ice stream and its bed, because in this zone lies the crucial determinant of ice movement. Glaciologists agree that water lubrication must be an important factor in allowing ice streams to move so rapidly despite small driving stresses (small surface slopes), but just how the water effects the rapid sliding—whether it acts through the mechanism of a thin, approximately uniform sheet, through channels incised in the underside of the ice, or through some other mechanism—is

The field survey during the first season of the program (1983-84) comprised seismic recordings at ~300 sites along three lines at angles of 60° to one another, over an area of $\sim 10 \text{ km}^2$. Geophone spreads were generally ~720 m long, with 30-m geophone spacings. All three components of motion were recorded so as to yield both P-wave and S-wave arrivals. Shots ranging

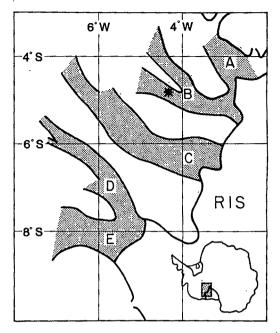

Fig. 1 Location map of ice streams along the Siple Coast of West Antarctica. An index map of Antarctica is in the lower right-hand corner. RIS, Ross Ice Shelf. Stippled areas are ice streams; the measurement site on ice stream B is marked by an asterisk. Standard grid coordinates are shown: in this rectangular system, 0° of longitude lies along the Greenwich meridian; and 0° of latitude passes through the South Pole.

in size from 0.15 to 0.45 kg were fired in shot holes ~20 m deep at spread centres and at various distances up to 4 km from the ends of the spreads. All the data were recorded on a digital recording system which was designed and built at the Geophysical and Polar Research Center. The system has a dynamic range of 84 dB and, for these experiments, sampled each of 24 channels at 0.4-ms intervals.

The existence of two reflectors near the base of the ice is seen very clearly in the seismogram of Fig. 2. In this example, the second echo is actually stronger than the first. The entire doubleecho pattern is repeated 21 ms later in secondary ('ghost') seismic waves that have travelled upward from the shot to be reflected first from the surface of the glacier and then from the bed. All of the travel times in Fig. 2 have been reduced for 'normal move-out', so that reflections from a flat, level surface

Table 1 Porosities calculated by comparing v_p as measured on ice stream B with laboratory measurements

Sample	f (kHz)	$\frac{\Delta v_{\rm p}}{({ m m~s}^{-1})}$	Porosity	Ref.

	Unweigh	ted mean	0.39 ± 0.06	

f is the frequency in the laboratory measurements, and Δv_p is the velocity correction relative to low frequency. Error figures on porosities correspond to a velocity uncertainty of ±120 m s⁻¹, compounded, in an r.m.s. sense, of the uncertainty in measured velocity of $\pm 100 \text{ m s}^{-1}$, and assumed uncertainty in Δv_p of $\pm 50 \text{ m s}^{-1}$, and a characteristic r.m.s. scatter in the laboratory data of $\pm 40 \text{ m s}^{-1}$. We use an unweighted mean because we view all of the standard deviations as equally valid estimates of a single value applicable to all the measurements.

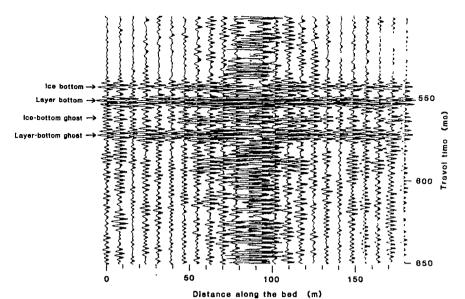

Fig. 2 Seismogram showing ice-bottom, layerbottom, and ghost echoes, as marked. All traces have been adjusted for 'normal move-out'.

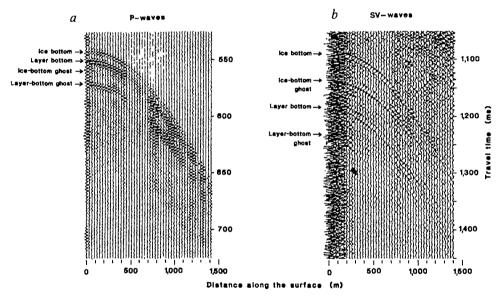

Fig. 3 Sequences of seismograms depicting 'wide-angle' (oblique) reflections. Not corrected for normal move-out. a, P-wave reflections; b, SV-wave reflections.

will appear at the same time regardless of the different horizontal distances between the shot and the various geophones.

The seismogram of Fig. 2, which was recorded along a direction parallel to the ice movement, depicts two level, coherent, reflecting surfaces separated by a travel-time difference (δt) of 10 ms. At a P-wave speed (v_p) in the layer of 1,600 m s⁻¹, that value of δt corresponds to a layer 8 m thick.

The wave speed in the layer was determined by means of 'wide-angle' (oblique) reflections over the section shown in Fig. 2. (The change in the travel-time difference between the two reflections as the shot and detectors are moved symmetrically outwards from the centre in opposite directions is a measure of the wave speed between the two reflectors.) The wide-angle profile (Fig. 3a) reveals that there is little change in the reflection-time difference between the two reflectors, which means that v_p in the layer is low compared with v_p in the ice (3,830 m s⁻¹). Thus, we are not seeing a basal layer within the ice. Numerical inversion of the wide-angle travel times yielded $v_p = 1,600 \pm 100 \,\mathrm{m \, s^{-1}}$ in the layer. This precision was made possible by the large signal-to-noise ratio and the high frequency of the echoes, which permitted a timing precision of 0.2 ms. The inversion procedure fully considers the dip of both the top and bottom of the layer as well as the ray bending caused by the vertically inhomogeneous velocity structure near the surface of the ice stream.

S-wave reflections from the upper and lower surfaces of the layer were recorded also (Fig. 3b), but with a δt that is 11 times as great as that for P-waves. This indicates an S-wave speed (v_s) of only $150\pm10~{\rm m~s^{-1}}$ in the layer. In the Earth, v_s values this low are found only in very porous material under low effective (differential) pressure (the difference between the overburden pressure, which tends to force the grains more tightly together and thus increase the rigidity of the solid framework of the sediment, and the pore-water pressure, which tends to weaken the contact between the grains). Beneath ice stream B this must mean a saturated sediment, in which the weight of the thousand metres of overlying ice is supported principally by the pore fluid

Along the direction of ice movement the subglacial reflecting horizons are clearly parallel to the ice bottom (Fig. 4a). The occurrence of more than one reflector suggests some stratification within the layer; the indicated strata are all nearly flat in the upstream-downstream direction. Transverse to the ice movement, however, there is much less continuity in the subglacial reflectors, and several sloping features appear (Fig. 4b). Most striking is the hump, occurring at ~ 0.8 km along the profile, that seems to rise near, or even to, the base of the ice. Since no deeper reflectors can be seen, it appears that

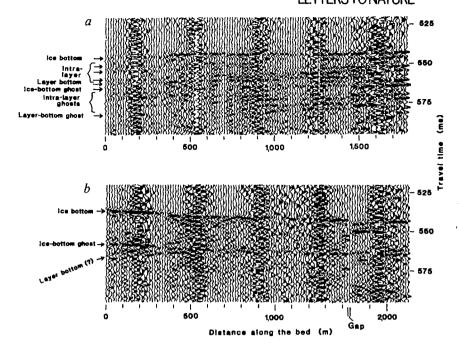

Fig. 4 Seismic reflection sections, each comprising five individual seismograms. Corrected for normal move-out. a, Section parallel to direction of ice movement; b, section transverse to ice movement.

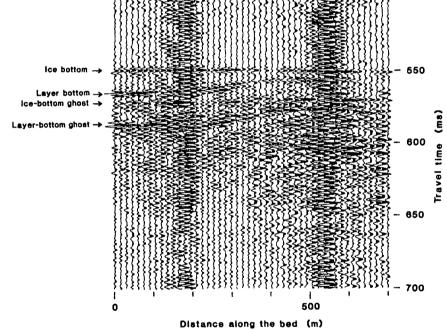

Fig. 5 Seismic reflection section transverse to ice movement, comprising two individual seismograms. Corrected for normal move-out.

locally, the layer nearly or entirely pinches out. Another section transverse to the ice stream (Fig. 5) shows a coherent layer-bottom reflection across the entire 0.8 km with a clear topographic relief of 8 m (10 ms). The maximum layer thickness on this section is 12 m (15 ms). From the available data we estimate an average thickness of 5 or 6 m.

The picture that emerges from the longitudinal and transverse sections is one of ridges and valleys in the basal surface of the sub-glacial layer, trending parallel to the axis of the ice stream. The alignment of these features along the direction of movement suggests that they are formed by erosion. It is significant to our model of a deforming bed¹ that there is no reflection of the ridges and troughs in the glacial/sub-glacial interface.

In a porous, saturated sediment, v_p depends primarily on the porosity n (and therefore the density), whereas v_s is most sensitive to the effective pressure ΔP . We can therefore estimate both n and ΔP using the v_p and v_s we have observed for the layer. Because $v_s \ll v_p$, both the rigidity and the incompressibility of the sedimentary frame are small compared with the bulk incom-

pressibility, κ , which then can be expressed simply as $\kappa = [(1-n)\beta_s + n\beta_w]^{-1}$, wherein β_s and β_w are the compressibilities of the sedimentary particles and the water, respectively. For a typical rock particle, we take $\beta_s = 2.6 \times 10^{-11} \,\mathrm{m}^2 \,\mathrm{N}^{-1}$, and for fresh water at $0 \,^{\circ}\mathrm{C}$, $\beta_w = 5.0 \times 10^{-10} \,\mathrm{m}^2 \,\mathrm{N}^{-1}$. From the seismic measurements, on the other hand, $\kappa = \rho v_p^2$, where the bulk sediment density $\rho = (1-n)\rho_s + n\rho_w$; ρ_s is the density of the sedimentary particles and ρ_w is the density of fresh water. We take $\rho_s = 2.6 \times 10^3 \,\mathrm{kg} \,\mathrm{m}^{-3}$ and $\rho_w = 10^3 \,\mathrm{kg} \,\mathrm{m}^{-3}$. Equating the two expressions for κ , we obtain $n = 0.365 \pm 0.075$ for $v_p = 1.600 \pm 100 \,\mathrm{m} \,\mathrm{s}^{-1}$.

Comparisons can also be made with laboratory and in situ measurements of v_p versus n in saturated sediments, but two corrections are needed. First, because most of the published values of v_p refer to sediments saturated with sea water and are corrected approximately to standard laboratory temperature and pressure, we must add a correction of $100 \, \mathrm{m \ s^{-1}}$ (ref. 7) to our measured velocity, which refers to fresh water at $0 \, ^{\circ}\mathrm{C}$ and a glaciostatic pressure of $9 \, \mathrm{MPa}$.

Table 2 Effective pressures (ΔP) calculated by comparing v_s as measured on ice stream B with laboratory measurements

Sample	ΔP (kPa)	Ref.
Artificial sand	40 ± 5	15
Silt	60 ± 5	16
Silty clay	30 ± 5	16
Potter's clay	120 ± 5	16
Marine silt-clays	70 ± 50	17*
Angular-grained material	15 ± 5	17†
Sands	25	18
Clays and silts	60	18
Unweighted mean	50±40	

Error figures for ΔP correspond directly to a velocity uncertainty of ±10 m s⁻¹ except in the case of the marine silt-clays¹⁷, for which a range of observed curves was taken into account. In calculating the standard error estimate for the mean, we have assumed a standard deviation of ± 50 kPa in ΔP for each sample.

* From Fig. 2 in ref. 17, using the supplementary relation: depth= $\Delta P/(\rho-\rho_{\rm w})g$, where g is the acceleration of gravity.

† From equation (6) in ref. 17.

Second, most laboratory measurements are made at frequencies between 100 kHz and 1 MHz, whereas our seismic frequencies are only ~ 400 Hz. Standard Biot theory^{8,9} with n = 0.4 (to be justified below) leads to a limiting high-frequency wave speed that is ~100 m s⁻¹ higher than the low-frequency speed. We have, therefore, added to our field measurements approximate frequency-effect corrections (Δv_p in Table 1) calculated according to standard theory¹⁰. These corrections are in approximate agreement with those measured for 1 MHz for various sediments, but because Δv_p depends on permeabilities in the sediment samples that had to be estimted, we assume an uncertainty in Δv_p of ± 50 m s⁻¹. Fuller details will be given elsewhere.

The porosities obtained from these comparisons show considerable scatter (Table 1) but are in satisfactory agreement with the value calculated above by linearly combining compressibilities and densities. It therefore seems safe to conclude that n in the sub-glacial layer is close to 0.4, although probably a bit less. That is is close to 0.4 and not 0.3 or less is significant, as it strongly suggests that the sub-glacial material is dilated and deforming1.

From v_p and ρ in the layer we can calculate that the acoustic impedance of the sediment is close to that of the ice. This explains how the echo from the bottom of the sediment could be stronger than that from the base of the ice. Echo amplitudes vary widely over the survey area, however; they will be considered in detail elsewhere.

The other quantity we wish to estimate is ΔP , since it is critical to the shear strength of the medium. The best measure of ΔP is v_s , because in an unconsolidated sediment v_s depends principally on the intergranular friction, and therefore on the intergranular pressure. Again, comparison with several experimental values leads to a considerable uncertainty (Table 2); nevertheless, all estimates of ΔP lie in the range 15-120 kPa. We adopt the mean value of 50 ± 40 kPa for ΔP in the sub-glacial layer.

We conclude that at least at one location, an active Antarctic ice stream is underlain by a layer of saturated sediment ranging in thickness from zero or nearly zero to at least 12 m, with an average of 5 or 6 m. The layer varies much less in thickness parallel to the direction of ice movement than normal to it; because its upper surface is planar, this gives the impression of a series of longitudinal grooves in the substrate beneath the layer. The low seismic wave speeds in the layer indicate that the material has a porosity of ~0.4 and is saturated with water at a pore pressure only ~50 kPa less than the glaciostatic pressure (9 MPa). Because these characteristics imply that the subglacial material is very weak¹, we believe that the sub-glacial layer is deforming and eroding the stationary surface below, and that it is deformation within the layer rather than deformation in the ice or basal sliding that is the principal component of ice-stream movement.

The field program is a cooperative effort among investigators from the University of Wisconsin, the Ohio State University, NASA and the University of Chicago. We thank B. R. Weertman, J. E. Nyquist, R. Flanders, S. Shabtaie, D. G. Schultz, K. C. Taylor, Jr and J. Dallman for help with field work, L. A. Powell. B. D. Karsh, R. B. Abernathy, W. L. Unger, and Weertman for engineering assistance, and A. N. Mares and S. H. Smith for manuscript and figure preparation. Financial support was provided by NSF under grants DPP81-20322 and DPP84-12404. This is contribution number 447 of the University of Wisconsin-Madison, Geophysical and Polar Research Center.

Deformation of till beneath ice stream B, West Antarctica

R. B. Alley, D. D. Blankenship, C. R. Bentley & S. T. Rooney

Geophysical and Polar Research Center, University of Wisconsin-Madison, 1215 West Dayton Street, Madison, Wisconsin 53706, USA

The behaviour and possible instability of the West Antarctic ice sheet depend fundamentally on the dynamics of the large ice streams which drain it. Model calculations show that most icestream velocity arises at the bed1,2, and radar sounding has shown the bed to be wet³, but the basal boundary condition is not well understood. Seismic evidence from the Upstream B camp (UpB) on the Siple Coast of West Antarctica4 shows that the ice stream there rests on a layer of unconsolidated sediment averaging 5 or 6 m thick, in which the water pressure is only ~50 kPa less than the overburden pressure. Because this thin layer occurs well inland beneath an active ice sheet and rests on a surface showing flutes characteristic of glacial erosion⁵, we presume that it is glacial till. We propose here that deformation within the till is the primary mechanism by which the ice stream moves, and we discuss implications of this hypothesis.

Three distinct lines of evidence relating to till porosity, force balance, and water balance indicate that the till at UpB is deforming; we present each of these here. First, lodged basal till has a porosity of ≤30%, whereas deformation of till causes dilation and porosity of ~40% (refs 6-8). The seismically determined porosity of ~40% for till at UpB⁴ is consistent with active deformation but too high for lodged till.

Second, we estimate that the basal shear stress is about twice the strength of till at UpB, so that the till should be deforming.

The strength of till can be estimated from measured properties of deforming till, collected by Boulton and co-workers⁶⁻⁹ beneath Breidamerkurjökull in Iceland. Briefly, Boulton found that the basal-ice velocity of Breidamerkurjökull arises largely from deformation of a dilated till layer of 40% porosity, that large stress concentrations occur locally during deformation, and that the dilated structure collapses and till strength increases by a factor of 1.6-4 if the strain rate is too low.

Because of the large stress concentrations in deforming till. ice-stream flow would dilate and deform lodged, low-porosity till if the average basal shear stress, τ , exceeded the strength of dilated till, τ_d . This is because, if the till at UpB were lodged, then the basal-ice velocity would arise from sliding across a water layer that reduced ice-bed contact to local patches. Weertman¹⁰ has shown that total ice-bed contact area would have to be reduced greatly to allow sliding at ice-stream velocities, so that the local shear stress in patches of contact would significantly exceed 4τ . However, the strength of lodged till is $<4\tau_d$ (refs 6-8), so that local mobilization of till would occur for $\tau \ge \tau_{\rm d}$. The stress concentrations caused by deformation would then mobilize adjacent, lodged till to form a continuous deforming layer that would thicken to intersect bedrock or until the strain rate became too small to generate stress concentrations large enough to mobilize more till. (Till would also be mobilized locally for some range of $\tau < \tau_d$, but the average basal shear stress would not be large enough in such conditions to deform a continuous layer of till.)

Boulton⁹ argues that till obeys a Coulomb-type failure criterion, so we let $\tau_d = \Delta P \tan \phi_d$, where ΔP is the excess of overburden pressure over water pressure and tan ϕ_d is the internal friction. (We have set cohesion to zero in the failure criterion, in accordance with the observations of Engelhardt et al.11 and because we expect dilation of till to disrupt the short-range electrostatic forces between clay particles that cause the cohesion in saturated, lodged till.) Till is deforming at Breidamerkurjökull, so τ must be $\geq \tau_d$ there. Using measured ΔP (ref. 7) and basal shear stress calculated from the geometry of Breidamerkurjökull9, we estimate from the Coulomb failure criterion that tan $\phi_d \le 0.15$. (Direct measurements of recently deformed till at Breidamerkurjökull⁶⁻⁸ using a shear box give values of tan ϕ_d equal to or slightly larger than that reported here, but laboratory shear tests consistently overestimate the strength of materials undergoing slow, large-scale deformation¹².) At UpB, $\Delta P =$ 50 ± 40 kPa (ref. 4); if internal friction of till is similar at UpB and Breidamerkurjökull, then $\tau_d \leq 8 \pm 6$ kPa at UpB.

The driving stress for ice flow at UpB is ~ 19 kPa, calculated from the familiar formula: driving stress = ρgh tan α , where the ice density $\rho = 920$ kg m⁻³; the gravitational acceleration g = 9.8 m s⁻²; the ice thickness h = 1,050 m, and the surface slope tan $\alpha = 0.002$ (ref. 13). The driving stress is resisted by gradients in stretching stress and by side drag as well as by the basal drag, τ , but a force-balance calculation for the ice stream by Whillans indicates that basal drag is the major resistive force. We have reached the same conclusion independently, and estimate that $\sim 95\%$ of the driving stress is balanced by basal drag at UpB, so that $\tau \approx 18$ kPa. This is more than twice the best estimated value of τ_d at UpB, so we expect till deformation to be occurring there.

The third argument for till deformation comes from a water-balance calculation. As noted above, if till is not deforming then ice-stream velocity must arise from sliding of ice over a rigid substrate lubricated by water. Weertman¹⁰ estimates that fast sliding requires a water film of thickness $d \approx 5$ mm or greater. At the head of an ice stream fed by a catchment area of length $L \approx 400$ km and width $F \approx 4$ times as wide as the ice stream¹³, the existence of fast sliding requires production averaged over the catchment area of a thickness of water per unit time, λ , given by¹⁰: $\lambda = d^3 \rho g \tan \alpha (12 \eta L F)^{-1}$, where $\rho g \tan \alpha$ is the pressure gradient driving water flow in the ice stream (assuming bed slope is of the same magnitude as surface slope or smaller¹³)

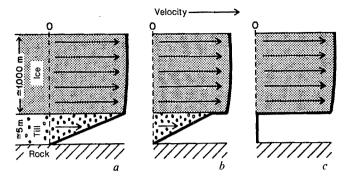

Fig. 1 Possible models for an ice-stream bed. a, Till deformation only; our model for UpB. b, Till deformation plus basal sliding; our model for near the grounding line of line stream B. c, Basal sliding only; not realized on ice stream B.

and $\eta = 1.8 \times 10^{-3}$ Pa s is the viscosity of water¹⁰. The minimum water production for fast sliding is then $\lambda = 2 \text{ mm yr}^{-1}$. We consider this much water production to be unlikely because: (1) the Byrd borehole, in the catchment area of ice stream D. showed that net basal freezing rather than melting occurs over some distance up-glacier of the borehole¹⁵, and the catchment of ice stream B is sufficiently similar to that of ice stream D in surface mass balance, surface topography, bed topography and ice thickness13 that we expect net basal freezing in parts of the ice-stream-B catchment; (2) in numerical experiments, Budd et al. 16 were able to generate a melt rate of 2 mm yr⁻¹ for most of the catchment only by increasing the geothermal heat flow by 50% above the value they expected based on the geology of West Antarctica; their expected value has been confirmed by measurements in the Byrd Station borehole^{17,18}; and (3) ice stream B and its catchment are underlain by ≥1 km of sedimentary rock^{19,20} that may have sufficient permeability²¹ to drain a significant amount of water. The amount of water available to lubricate sliding would be reduced further if some water flowed in channels rather than in a Weertman film²². It is thus unlikely that enough water is supplied to the ice stream to allow high velocities near its head by sliding. (Note, however, that water generated beneath the ice stream may form a film at the ice-till interface²³, so that both till deformation and water-lubricated sliding may be important near the grounding line (Fig. 1).)

The above arguments show that most ice-stream velocity arises from till deformation, and we now use this result to show that the entire thickness of till at UpB is deforming. As noted above, stress concentrations in active till increase with increasing strain rate, $\dot{\varepsilon}$. If $\dot{\varepsilon}$ were to exceed $\dot{\varepsilon}_b$ the minimum strain rate required to cause stress concentrations large enough to mobilize lodged till, then active till would mobilize subjacent, lodged till until the strain rate was reduced to $\dot{\varepsilon}_l$ or until till activation reached bedrock. We thus expect $\dot{\varepsilon} = \dot{\varepsilon}_l$ if active till overlies lodged till and $\dot{\varepsilon} \ge \dot{\varepsilon}_l$ if active till reaches bedrock. The average simple strain rate in till is u/h_b , where u is the velocity of the till at its upper surface and h_b is the thickness of the active layer. At Breidamerkurjökull⁹, where active till overlies lodged till, $u = 16 \text{ m yr}^{-1}$, $h_b = 0.5 \text{ m}$ and $\dot{\varepsilon} = 32 \text{ yr}^{-1} = \dot{\varepsilon}_l$. At Blue Glacier¹¹, where active till reaches bedrock, $u = 4 \text{ m yr}^{-1}$, $h_b = 0.1 \text{ m}$ and $\dot{\varepsilon} \simeq 40 \text{ yr}^{-1} \ge \dot{\varepsilon}_h$ At UpB, for little slip between ice and till, $u \simeq 450 \text{ m yr}^{-1}$ (ref. 24) and $h_b \simeq 6 \text{ m}$, so $\dot{\varepsilon} \simeq 75 \text{ yr}^{-1}$. As this is much greater than $\dot{\varepsilon}_l$ at Blue Glacier and Breidamerkurjökull, and there is no reason for \dot{e}_i to be grossly different at UpB, we conclude that the entire thickness of till at UpB is deforming.

Given that the entire thickness of till at UpB is deforming, we can now calculate the fluxes of till and water beneath UpB and the generation rates in the catchment area required to sustain these fluxes if they are steady-state values. Water moves by advection with till and by conduction through till. From Darcy's law, the conductive flow velocity is $u_c = k/\eta (dP/dx)$ where

 $k = \text{till permeability} \approx 1.6 \times 10^{-13} \,\text{m}^2(\text{ ref. 7}), \, \eta$ -dynamic viscosity of water = 1.8×10^{-3} Pa s, and (dP/dx) = pressure gradient from weight of ice = $\rho g \tan \alpha \approx 18 \text{ Pa m}^{-1}$ (again assuming that bed slope is of the same magnitude as surface slope or smaller¹³). The flow velocity, u_c , is then $1.6 \times 10^{-9} \,\mathrm{m \, s^{-1}} \simeq 0.05 \,\mathrm{m \, yr^{-1}}$. The depth-averaged advective flow velocity, \bar{u}_a , is given by $\bar{u}_a = \bar{u}n$, where \bar{u} is the depth-averaged velocity of bulk till and n = 0.4 is the till porosity⁴. For no-slip boundaries and any reasonable till rheology (such as linearviscous, power-law creep with finite exponent, or Bingham substance) velocity will vary almost linearly from 450 m yr⁻¹ at the ice-till interface²⁴ to zero at the till-bedrock interface, so $\bar{u} = 225 \text{ m yr}^{-1}$ and $\bar{u}_a = 90 \text{ m yr}^{-1}$. This is more than three orders of magnitude larger than the conductive velocity, so essentially all the water flow is advective.

The total water flux per unit width of ice stream is $h_h \bar{u}_a w$, where $h_b \approx 6$ m is the till thickness and w is the ice-stream width. In steady state, this flux corresponds to an average watergeneration rate of thickness λ over an area $(FL+L_2)w$, where $L_2 \simeq 100 \, \text{km}$ is the length of the ice stream above UpB, $L \simeq$ 400 km is the length of the catchment area, and $F \approx 4$ is the width of the catchment area feeding unit width of the ice stream¹³. Then $\lambda = h_b \bar{u}_a (LF + L_2)^{-1} \approx 0.3 \text{ mm} \text{ yr}^{-1}$. This is almost an order of magnitude less than the 2 mm yr⁻¹ melt rate needed for Weertman sliding at the head of the ice stream, and is consistent with our knowledge of water generation in the catchment area. The average erosion rate of rock can be obtained from the same calculation by replacing porosity, n, by rock fraction, 1-n, and is $\sim 0.5 \text{ mm yr}^{-1}$.

We thus hypothesize that the velocity of ice stream B near UpB arises largely from deformation of a sub-glacial till layer (Fig. 1). This hypothesis suggests several corollaries, which include: (1) the basal boundary condition for ice-stream flow depends on the constitutive relation for till; (2) the till flux beneath UpB is equivalent to steady-state erosion of ~0.5 mm yr⁻¹ of rock over the catchment area and the upstream part of the ice stream; (3) this till flux requires deposition of morainal banks or 'till deltas' at the grounding line; recent mapping of the grounding line²⁵ is consistent with the existence of such deltas; (4) the fluted nature of the till-rock interface at UpB may be a characteristic erosional consequence of deforming till²⁶; and (5) variations in till thickness over flutes may cause fluctuations in basal drag that affect ice-stream flow, with higher drag over bedrock ridges and lower drag over troughs. Our work also suggests the possibility that other ice streams and other wet-based regions of ice sheets²⁷ may rest on till. We are conducting further field work and analysis to test these hypotheses.

Corals on seamount peaks provide evidence of current acceleration over deep-sea topography

Amatzia Genin, Paul K. Dayton, Peter F. Lonsdale & Fred N. Spiess

Scripps Institution of Oceanography, University of California, San Diego, La Jolla, California 92093, USA

Geological and physical studies of seamounts have suggested the existence of distinct deep-sea habitats, characterized by exposed rocky bottom and a unique current regime 1-9. However, few biological data have been collected for deep seamounts 10-12. Here we present some of the first quantitative observations of hard-bottom (non-hydrothermal) fauna in the deep sea. These observations show that black corals (antipatharians) and horny corals (gorgonians) present on the slopes of a multi-peaked seamount are more abundant near peaks, compared with mid-slope sites at corresponding depths. On narrow peaks corals are most abundant on the crest, whereas on wide peaks, coral densities are highest at the edge of the crest. The abundance of corals also increases on knobs and pinnacles. Physical models and observations2.4-9,13-15, together with our direct measurements, suggest that the seamount topography affects the local current regime. Corals appear to benefit from flow acceleration, and some of their patterns of distribution can be explained by current conditions. These results suggest that suspension feeders have some potential as indicators of prevailing currents at deep hard-bottom sites.

We made our observations on Jasper Seamount, which is an extinct volcano 3.5 km high 30 km in diameter, built on the 4,200-m-deep abyssal Pacific floor, about 550 km south-west of San Diego, California. It has a multi-peaked summit area (Fig. 1) with two of the peaks rising higher than 600 m depth. Most of the summit area consists of bare basaltic rock, with thin pockets of sediment in some depressions between the peaks. A rich and diverse fauna, dominated by sedentary suspension feeders such as sponges, black corals, horny corals, anemones and tunicates, was discovered in our photographic survey of the seamount. The most common species on the upper slopes of the seamount is the spiral black coral, Stichopathes sp., which occupies rocky substrata at depths from 550 m to 1,150 m, where it sometimes forms 'forests' with densities of up to 20 colonies per m². In areas partially covered with sediment, Stichopathes is found only on protruding rocks; it is absent in areas with 100% sediment cover. Along its upper range, the Stichopathes zone overlaps a rich sponge zone. Gorgonians and branched antipatharians are the dominant taxa on the rocky bottom at depths below the Stichopathes zone. However, coral densities at these greater depths are much lower than in the Stichopathes zone.

Variations of coral abundances, at any depth, are associated with the local topography, on three different scales:

(1) Over the entire seamount, Stichopathes densities are significantly higher near peaks than at mid-slope sites at corresponding depths (Fig. 2). For example, the average Stichopathes

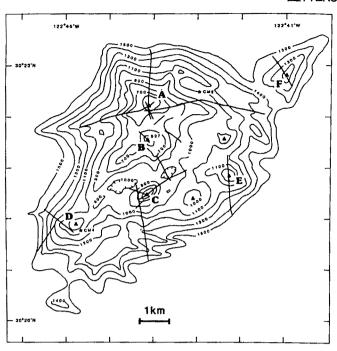

Fig. 1 The summit of Jasper Seamount, showing bathymetry, designated peak names, locations of current-meter moorings (*), and photographic transect lines (heavy black lines). Contours are in metres. Photographs were taken by the Deep-Tow instrument package²⁰ at ~10-m intervals. The camera-to-bottom distance was recorded when each photograph was taken, allowing computation of areas and animal densities.

density near peak C, between 700 and 750 m depth, is about 15 colonies per m² (Fig. 3), which is about three times the mean density of the species on slopes at the same depth interval (Fig. 2). Similarly, densities of gorgonians near peak F, at a depth of 1,170-1,250 m (Fig. 3), are more than five times higher than at the same depth interval on the slopes.

(2) On the peaks, the species exhibit two distribution patterns: on wide peaks (diameter > 1 km), with a flat or gradually sloping top, highest densities are found along the perimeter of the top, and lower densities on the top itself (Fig. 3, peaks A and F); on narrow, tapering peaks, highest densities are found on the crests (Fig. 3, peak C).

(3) On a smaller scale, *Stichopathes* exhibits increased abundances on knobs and pinnacles. For example, a sharp increase in density is found on the small knobs at 1.4 km and 3.9 km along the transect across peak A (Fig. 3).

Why are corals more abundant near peaks? We assume that concentrations of food and larvae in waters impinging on the seamount are independent of the local topography, that is, the average concentrations of food and larvae in waters impinging on a peak and on a slope at the same depth are similar. However, fluxes of food and larvae could vary at different sites due to topographic effects on water flow. Within a certain range of current speed, areas of flow acceleration are expected to be favourable for recruitment and growth of passive suspension feeders; this may be attributed to either the 'settlement pathway'. in which a site is colonized by relatively more recruits simply because more water, and hence more larvae, are flowing by per unit of time, or the 'feeding pathway', in which an increase of water flow past suspension feeders results in increased feeding and growth rates 16-18. This may also be critical for the survival of small recruits. Both pathways can lead to long-term integration of current conditions by the animals.

There are two lines of evidence for intensified water flow near peaks, where the abundance of corals is relatively high. First, our direct current measurements on Jasper Seamount (Fig. 4), although short-term and limited to two stations, showed that the mean total speed near a peak was about twice the mean speed at the same depth but on a mid-slope site. Second, observations on other seamounts^{9,13-15} have demonstrated hydrographic conditions near the summit which differ from those along the slopes, because the upwelling requires acceleration over the top of the seamounts.

The distribution of corals on wide peaks can be explained by predictions of physical theory. When water is upwelled above wide topography, vortex lines are compressed and anticyclonic motion is induced, because of conservation of potential vorticity^{4,5}. The resulting flow-field is a combination of the velocity induced by this anticyclonic component and the free-stream velocity. Thus, looking downstream, flow acceleration occurs on the left side of the topographic feature (in the Northern Hemisphere) and deceleration above the centre and right side of the peak^{3,4,7}. As this theory has been developed for a uniform and steady flow, the validity of the model for strong tidal currents (see, for example, Fig. 4) is less certain. A possible effect of the tide would be a switch of the anticyclonic acceleration-deceleration zones. The overall mean velocity pattern would therefore comprise alternating periods of acceleration on the peak's edges and recurrent deceleration trend over the centre. This postulated velocity pattern is consistent with the lower densities of corals observed at the centre of the wide peaks of Jasper Seamount (Fig. 3). Furthermore, the combination of tidal fluctuations and a general southward flow in the vicinity of the seamount (Fig. 4; ref. 19) could result in a stronger average acceleration on the eastern side of the seamount; this could explain why Stichopathes is about twice as dense on the eastern edge of the main seamount peak as on the western edge (Fig. 3, peak A).

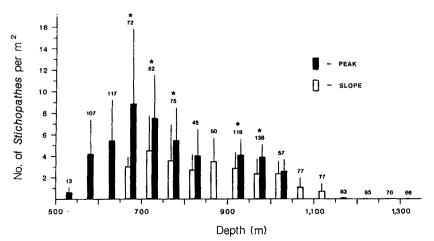

Fig. 2 Densities of Stichopathes (mean \pm s.d.) at different depth intervals on Jasper Seamount. The photographs were divided into those near peaks (solid bars) and those >150 m below a peak (open bars). Only photographs which exhibited <10% sediment cover were included in the computation. Stars indicate the intervals in which the mean nearpeak density is significantly higher than the mean mid-slope density (P<0.001, Mann-Whitney Utest). The number of photographs taken at each depth interval is indicated above the corresponding bar.

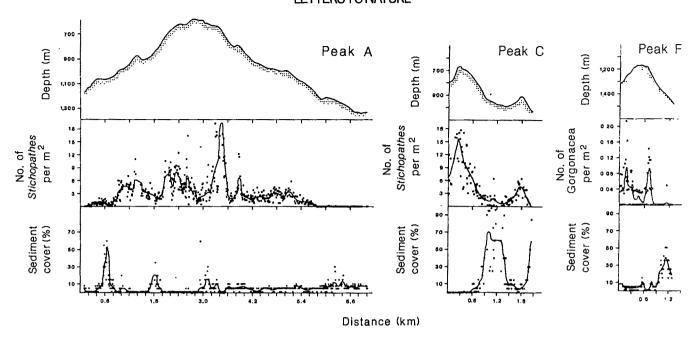

Fig. 3 Bathymetry, animal densities and sediment cover in transects across peaks A. C and F. Each dot indicates the animal density or sediment cover in a single photograph. Solid lines indicate 9-point running means. The transects are from west to east across peaks A and C, and from south-east to north-west across peak F. Sediment cover, which can have a deleterious effect on suspension feeders^{21,22}, cannot explain why corals are more abundant near peaks and on pinnacles. For example, the distribution pattern exhibited by Stichopathes close to peak C occurs along the initial 600 m of the transect, which is sediment-free. Similarly, distinct changes in gorgonian densities near peak F occur in an area where the sediment cover is low and nearly uniform. Overall, the correlation between sediment cover and Stichopathes density between 527 and 1,150 m depth is low but significantly different from zero (Kendall rank correlation = -0.2, P < 0.01, n = 1,359).

Fig. 4 (Right) Current velocity and progressive vector diagram of records taken near peak D (CM 4) and at a mid-slope site east of peak A (CM 2), both at a depth of ~1,000 m. Dots on the progressive vector diagram of CM 4 indicate 24-h intervals. The mean current speed (15min averages) was significantly higher (P < 0.001, Student's t-test) near the peak (4.9 cm s⁻¹) than at the mid-slope site (2.7 cm s⁻¹). Measurements were made with two SIO-Model 6 Savonius rotor current meters, deployed at 46 m above the bottom. Spectral analysis of these records indicates that the kinetic energy of internal waves near a critical frequency (0.5 cycles h⁻¹), in which internal waves are reflected parallel to the topographic slope^{8,23,24}, is negligible compared with the energetically dominant diurnal frequency. Such reflection, when present, may intensify water flow over seamounts and slopes8.

We conclude that the current regime is a key factor in determining community structure on the deep hard-bottom areas of Jasper Seamount, where suspension feeders are more abundant at sites of flow acceleration.

Monocular aniseikonia: a motion parallax analogue of the disparity-induced effect

Brian Rogers

Department of Experimental Psychology, University of Oxford, South Parks Road, Oxford OX1 3UD, UK

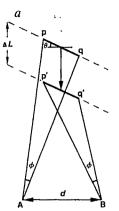

Jan Koenderink

Department of Medical Physics, University of Utrecht, The Netherlands

Mayhew and Longuet-Higgins have recently outlined a computational model of binocular depth perception¹ in which the small vertical disparities between the two eyes' views of a three-dimensional scene are used to determine the 'viewing parameters' of fixation distance (d) and the angle of asymmetric convergence of the eyes (g) (refs 2, 3). The d/g hypothesis, as it has been called⁴, correctly predicts that a fronto-parallel surface, viewed with a vertically magnifying lens over one eye, should appear to be rotated in depth about a vertical axis^{1,3-5}. We report here a comparable illusion for surfaces specified by monocular motion parallax information, which can be explained more simply by considering the differential invariants of the optic flow field. In addition, our observations suggest that the disparity-induced effect is not a 'whole field' phenomenon nor one limited to small magnification differences between the eyes^{1,4}.

The vertical magnification of one eye's image of a binocularlyviewed surface produces the impression of a surface rotated about a vertical axis through the fixation point. This effect was called the 'induced effect' by Ogle⁶ because he believed that horizontal disparities were 'induced' into the neural representations by a compensatory isotropic scaling mechanism acting to minimize the vertical size differences caused by eccentric fixation. Since horizontal disparities are affected by both the magnitude of any depth differences and the degree of eccentric fixation (g), the zero horizontal disparities in an induced effect stimulus have to be 'corrected' so that the relative distance and the slant of a surface can be perceived correctly. However, it appears that Ogle did not appreciate the more general significance that vertical disparities at other retinal locations apart from the vertical meridian provide a potential source of information about distance to the fixation point, as well as the angle of eccentric convergence. The mathematical proof for this has been independently provided by Gillam and Lawergren⁷ and Mayhew and Longuet-Higgins¹⁻³. In both cases, the induced effect is seen as a necessary consequence of a stereoscopic system which uses vertical disparities to determine the viewing system parameters.

As yet, there is little evidence that presence of vertical disparities in a stereogram actually gives a subjective impression of eccentric convergence but, as several authors have pointed out, this might be due to the presence of conflicting oculomotor information^{1,7}. However, the magnitude and the direction of the induced effect are both consistent with the d/g hypothesis³. Mayhew and Longuet-Higgins also argue the case for the induced effect being a global or 'whole field' phenomenon, since there could only be a single estimate of eccentric fixation angle and therefore only a single 'correction' would be applied to the horizontal disparities in the surrounding area^{1,4}. As additional evidence for their theory, they note that the magnitude of the induced effect does not increase when the vertical size difference is greater than about 4-6% 1.6. This would be predicted by their hypothesis since larger differences in size would imply impossibly large angles of asymmetric convergence^{1,7}. Both claims are examined in this paper.

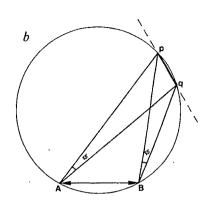

Fig. 1 In a, pq represents part of a surface slanting at an angle θ to the frontoparallel plane, which moves forward to p'q' at the same time as a monocular observer moves from A to B. It can be shown that the horizontal angle subtended at the eye ϕ will remain constant when $\tan \theta = \Delta L/d$. In contrast, since the surface is closer at B than A, the vertical angle subtended will increase. In b, the horizontal angle subtended again remains constant and the vertical angle subtended increases when the monocular observer moves from A to B towards an eccentrically placed slanting surface pq. The two situations differ only by an eccentric rotation of the lines of sight.

The disparity-induced effect can be perceived when one eye's image of a binocularly-viewed scene is magnified vertically. The motion parallax analogue of this illusion-monocular aniseikonia-was created by continuously magnifying and minifying the image projected to a single viewing eye during side-to-side movements of the observer's head8. The instantaneous monocular images of the scene at the end points of the lateral head movement necessarily correspond to the two simultaneous binocular views of the same scene when a meridional magnifying lens is placed over one eye. For all the observations reported in this paper, the image transformations for both the parallax and disparity-induced effects were effected electronically, rather than by optical means. The images consisted of either a single random dot pattern, or a pair of random dot patterns viewed independently by the two eyes, each subtending a 20°×20° visual angle. The disparity-induced effect was produced by increasing the vertical gain slightly on one oscilloscope and decreasing it slightly on the other. The horizontal widths of the patterns remained identical. To produce the parallaxinduced effect, the vertical gain of a single, monocularly-viewed oscilloscope was modulated according to the position of the observer's head. Thus the vertical size of the dot pattern was maximal at one end of travel and minimal at the opposite end of travel. Observers were asked to report the perceived orientation and shape of the random dot surfaces in the different experimental conditions.

With binocular viewing of the disparity-induced surface, our results replicate those of previous studies^{3,6,7}. Observers reported that the surface appeared to be slanting in depth with the right-hand side apparently closer than the left, when the right eye's image was vertically magnified, and vice versa for magnification of the left eye's image. Increasing the difference in vertical magnification between the two eyes increased the angle of perceived slant, as found previously.

With monocular viewing of the parallax-induced surface, a similar pattern of results was obtained. Observers reported that the surface appeared to be slanting in depth with the right-hand side closer than the left when the monocular image was progressively magnified with head movement to the right and vice versa. Again, the angle of perceived slant increased with an increase in the extent of vertical magnification/minification (for a constant head movement). In both the disparity-induced effect and its parallax analogue, the apparently slanting surfaces were

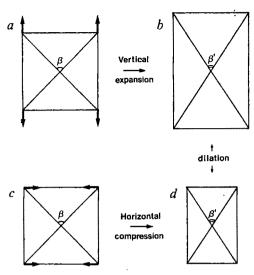

Fig. 2 The vertical expansion of the square pattern segment from a to b will produce the same amount of local and global deformation (as indicated by the change in the orientation difference between the diagonals $\beta \rightarrow \beta'$) as the horizontal compression of the same pattern segment from c to d. The transformed patterns, b and d, are related by a uniform or isotropic expansion.

always perceived as lying directly in front of the observer, rather than eccentrically to one side. In the case of the parallax-induced effect, the slanting surface was also perceived to approach and recede along a median path as the image expanded and contracted. This percept is entirely consistent with the geometry of the transformation, since the image of a slanting surface which approached an observer as he moved laterally towards the "closer" side, would indeed expand vertically, but remain of constant width (Fig. 1a).

The interpretation chosen by the visual system is, however, not the only one consistent with the image transformation. In fact, there are an infinite number of possible solutions (unlike the disparity-induced effect which has only one solution). For example, a surface positioned eccentrically and slanting with respect to the direction of gaze, would also generate an image whose vertical size increased and decreased with head movements whilst its horizontal size remained constant (Fig. 1b). This particular solution lies behind the explanation proposed by Mayhew and Longuet-Higgins to account for the disparityinduced effect¹. The fact that observers do not experience this perceptual outcome suggests that, for the parallax system, a vertical size change which accompanies a horizontal head movement is interpreted as a motion in depth rather than resulting from eccentric fixation.

Two additional sets of observations were made for the disparity- and parallax-induced effects. First, as mentioned above, the d/g hypothesis predicts that the induced effect should be 'whole field' phenomenon, since it seems unlikely that the visual system could entertain different, and therefore contradictory, estimates of the angle of eccentric convergence at the same time. Empirical evidence for the 'whole field' characteristic of the effect comes from the observation that an embedded region which is magnified in one eye's view does not appear to be slanted with respect to the surround^{1,5,9}. However, the perception of opposite induced effects in neighbouring spatial regions is possible in both the classical induced effect and the parallax analogue reported here. For example, if the images of the left and right halves of the random dot pattern seen by the right eye are minified and magnified respectively (with respect to the images seen by the left eye), subjects report that the left half of the pattern appears to be slanting closer to the left and the right half slanting closer to the right. According to the d/g hypothesis this could only be possible if the vertical disparities in the left half field were interpreted as indicating asymmetric convergence to the right, and in the right half field as indicating asymmetric convergence to the left. A comparable 'double' induced effect was also obtained for surfaces specified by motion parallax

The second piece of evidence cited in favour of the d/ghypothesis is that the induced effect does not increase with vertical magnifications greater than 4-6% 3,6. Indeed, this prediction was used by Frisby⁴ to discount Westheimer's finding that sensitivity to vertical disparities is much poorer than for horizontal disparities¹⁰. However, we have found that the apparent slant of induced effect surfaces does still increase monotonically right up to a 50% magnification difference, when induced effects specifying opposite slants are alternated every few seconds. At the 57-cm viewing distance used in the present experiments, the maximum possible magnification difference which could result from asymmetric convergence would be less than 7%.

Our proposed explanation of the parallax-induced effect is based on the use of differential invariants to describe the optic flow field¹¹⁻¹³. As Koenderink has shown, the slant of a surface is uniquely specified by the amount of deformation or shear in the flow field, if the extent of observer motion is known. Clearly, the vertical expansion of a monocular image, which underlies the parallax-induced effect, will produce the same degree of deformation in the flow field as a horizontal contraction of the same image (Fig. 2). Hence, the same surface slant is specified. What remains after the deformation component has been extracted is a simple divergence term which is positive in the first case and negative in the second. In the parallax-induced effect, the divergence term is clearly not ignored but instead is responsible for the apparent approach and recession of the slanted surface noted earlier.

Could the proposed explanation also account for the disparity-induced effect? Given that both the mathematical analyses of disparity and parallax transformations¹⁴ and their perceptual characteristics are so similar 15,16, it is tempting to speculate that the perceived surface slants seen in the disparity-induced effect are the result of having a visual system which uses the amount of deformation between the two binocular images as an indicator of surface slant¹⁷. If this were the case, then the visual system would be left to account for the isotropic size difference between the eyes (the divergence component). The human visual system may have evolved to use this as an indicator of eccentric fixation or it may simply be ignored. Hence, our explanation of the induced effect also allows for the angle of eccentric fixation to be recovered from the disparity field, but differs from the Mayhew and Longuet-Higgins interpretation in that this does not have to be done, even implicitly. According to the d/g hypothesis, vertical disparities are used to signal the angle of asymmetric convergence which is then used to scale horizontal disparities. The fact that vertical disparities do not appear to give the impression of asymmetric convergence, together with the other characteristics of the induced effects reported here, suggests that our proposed explanation may be more parsimonious.

New HLA DNA polymorphisms associated with autoimmune diseases

H. Festenstein*, J. Awad*, G. A. Hitman†, S. Cutbush*, A. V. Groves*, P. Cassell‡, W. Ollier* & J. A. Sachs*‡

Certain class II determinants of the human histocompatibility locus antigens (HLA) have been implicated in the aetiology of several autoimmune diseases, including rheumatoid arthritis (RA) and insulin-dependent diabetes mellitus (IDDM). HLA-Dw4 was the first HLA determinant found to be significantly increased in RA patients compared with controls¹, while Dw4 and Dw3 were found to be significantly increased in IDDM patients^{2,3}. When the HLA-DR system was defined, RA patients were found to have an increased frequency of DR4 and IDDM patients an increased incidence of both DR4 and DR3 (ref. 4) compared with controls. As the HLA-Dw specificities are narrower than the serologically defined DR specificities, it was of specific interest to the present study that Dw4, Dw10, Dw13, Dw14, Dw15 and DKT2 are included in DR4 (ref. 5). We describe here new restriction fragment length polymorphisms (RFLPs) and, together with the newly described serologically defined DQ specificity TA10 (ref. 6), test their prevalence and associations in controls and diseased patients. We find that the newly characterized DNA bands are present at a much higher frequency in RA and IDDM patients than in controls. These findings may lead to a greater understanding of the pathogenesis of such diseases.

The HLA class II region is considered to consist of five α -chain genes and eight β -chain genes; these are encoded in three subregions, HLA-DP, -DQ and -DR. The DR subregion contains one α -chain gene and three or four polymorphic β -chain genes, while the DP and DQ subregions each have two α - and two β -chain genes, all of which are polymorphic. The class II molecules encoded by these genes are transmembrane dimers consisting of an α - and a β -chain. Certain alleles of the HLA-DR series are in strong positive linkage disequilibrium with alleles of the DQ series (reviewed in ref. 7). The genetic basis of the DW determinants, determined by homozygous typing cells (HTCs) in mixed lymphocyte culture, remains controversial. It is our view that these determinants are encoded in the HLA-DR subregion but are not identical to the specificities of the DR segregant series 8,9 .

We first investigated the DR4 RFLP, using as reference DNA panels of HTCs covering all the Dw specificities. The DNA was digested with TaqI, PvuII, PstI and EcoRI, electrophoresed on

agarose gels, and the gels were then blotted onto nitrocellulose filters and hybridized with DR β , DQ β and DQ α probes. Out of 11 DR4⁺ HTCs tested, 3 were Dw4, 1 was Dw10, 2 each were Dw13, Dw14 and Dw15 and 1 was DKT2 (Table 1).

No differences were seen in the Southern blot patterns obtained after hybridization with the DR β probe (not shown). However, after TaqI digestion followed by hydridization with the DQ α probe, which detects DX and DQ genes^{10,11}, we observed clear differences in the Southern blot bands. This probably represents the $DX\alpha$ polymorphism first described by Hui et al. 12 and confirmed by others 13. Taq I digestion showed the DX α polymorphism to consist of 2.1-kilobase (kb) ('upper' = U) and 1.9-kb ('lower' = L) fragments; U and L correspond to the 2.2- and 2.1-kb bands described by Nepom et al.14 Two consanguineous DR4/Dw4 HTCs tested show different patterns; MCF contains the L fragment while BM14 contains the U fragment. All the other HTCs have one or other of these fragments; the two Dw13 HTCs also have different DX α RFLPs (Fig. 1). In addition, BM14 and MCF give different DQα RFLPs using PvuII (8 and 7.5 kb respectively, not shown); these probably also represent the DX α polymorphism, and we have now used this to investigate HLA associations in IDDM and RA. Our results suggest that DQ differences do not correlate with Dw definitions. Figures 2 and 3 show Southern blot patterns öbtained using the DQβ probe and EcoRI, PstI, PvuII and TaqI to digest the DNA. Two patterns, which we have called Ω and ϕ (see Table 1), were seen among the HTCs; when they are compared using BM14 (Ω) and MCF (ϕ) (Fig. 2), both of which are DR4/Dw4, the bands which distinguish most clearly between the two patterns are of 12 kb (Ω) and 4.4 kb (ϕ) using PstI, and 19 kb (Ω) and 13 kb (ϕ) using EcoRI, while with PvuII a 2.6-kb band is absent in Ω and present in ϕ . The patterns obtained on TaaI digestion (Fig. 3) are more complex, consisting of bands of 2.0, 2.3 and 2.5 kb for Ω and of 1.8, 1.95, 2.2, 2.4 and 2.6 kb for ϕ . The two DR4/Dw13 HTCs show different DOB RFLPs, as do the two DR4/Dw4 HTCs (Fig. 3). These results support our earlier findings that the DQ types detected using alloantisera do not materially affect HLA-Dw assignment and that the same Dw specificity can occur in cells that differ for HLA-DQ (ref. 15).

We next performed serological and monoclonal antibody studies of the DR4 cells using the FLEGG alloantiserum¹⁶ and the A10-83 monoclonal antibody (Maeda, 9w790) in a standard microcytotoxicity test. These reagents define a specificity designated TA10 (ref. 6) which splits DQw3 into DQw3.1 and DQw3.2 (see ref. 14) and which is associated with DR5-DQw3 and a subset of DR4. One of the two DR4/Dw4 HTCs was TA10-positive (MCF, ϕ) and the other (BM14, Ω) was TA10-negative (Table 1). The two DR4/Dw13 HTCs also had disparate TA10 typings. Table 2 shows the frequency of TA10 positivity in the DR4⁺, DR5⁻ controls. Positivity for the TA10 subtype of DQw3 coincides with the DQ $\beta\phi$ pattern in the small number of DR4⁺

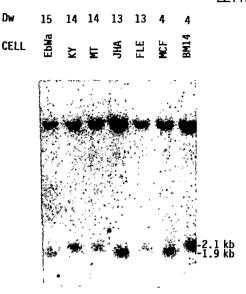

Fig. 1 DNA of homozygous DR4 cells digested with TaqI and probed with DQ α . The figure shows the DX α 'U' band at 2.1 kb and the 'L' band at 1.9 kb. The cell lines MCF, JHA and EbWa have the L band, whereas BM14, FLE, MT and KY have the U band.

Methods. Genomic DNA was either extracted from Epstein-Barr virustransformed cell lines derived from the HTCs shown in Table 1, or from peripheral blood lymphocytes from patients and controls. DNA (10 μ g) was digested for 16 h with EcoRI, PoulI or PstI at 37 °C, or with TaqI at 65 °C (enzymes from Boehringer Mannheim). The resulting DNA fragments were separated on 0.5% agarose gels by electrophoresis at 30 V for 18-20 h and then transferred 30 to nitrocellulose filters (Schleicher & Schuell). Fragments of HindIII-digested λ DNA were used as molecular size markers. The DNA probes used were labelled with $[\alpha^{32}P]dATP$ and $[\alpha^{32}P]dTTP$ (NEN) by nick-translation³¹. Before hybridization, the nitrocellulose filters were incubated for 2 h at 65 °C in 0.45 M NaCl/45 mM trisodium citrate (pH 7.0) and 10× Denhardt's reagent. The filters were then hybridized with the ³²P-labelled heat-denatured probe in 0.45 M NaCl/45 mM trisodium citrate (pH 7.0)/10× Denhardt's reagent/10% sodium dextran sulphate and 500 μg denatured salmon sperm DNA per ml of hybridization mix. After 16 h at 65 °C the filters were washed three times at 65 °C for 15 min each with 0.45 M NaCl/45 mM trisodium citrate (pH 7.0)/0.1% sodium dextran sulphate, three times at 65 °C for 15 min each with 0.15 M NaCl/15 mM trisodium citrate (pH 7.0)/0.1% sodium dextran sulphate, and three times at 65 °C for 15 min each with 50 mM NaCl/5 mM trisodium citrate (pH 7.0)/0.1% sodium dextran sulphate. The labelled fragments were then detected by exposing Kodak XAR-5 film with intensifying screens to the radioactive filters at -70 °C for 2-3 days.

HTCs. This was confirmed by Nepom et al.¹⁷ using a larger panel and may correspond to the DQR4 (Ω) and DQR5 (ϕ) patterns described by Cohen-Haguenauer et al.¹⁸. Although the TA10/DQ $\beta\phi$ association is not absolute in heterozygous individuals, as TA10 is included within DQ $\beta\phi$, it may define a DQ $\beta\phi$ subtype (Table 3). TA10 positivity is also associated with B44 in our DR4⁺ panel.

As all these new polymorphisms are associated with each other and with specific HLA determinants, we were able to construct three series of associated alleles, or preferential allelic associations (PAAs); one was based on the B8/DR3 haplotype, one on the DR4/B44 haplotype and one on the DR4/Bw62 haplotype, which includes alleles not only of the newly described RFLPs (see below) but also of TA10.

Disease associations were thus investigated in two ways. First, the incidence of the newly described polymorphisms was compared directly in patients and control subjects— $DX\alpha U$ and L; $DQ\beta\phi$ and Ω ; and $DQ\beta T6$ and TA10 positivity and negativity. $DQ\beta T6$ was defined by a 6-kb fragment obtained with the $DQ\beta$ probe following TaqI digestion and was present in all the DR4 HTCs (Fig. 3) but was absent in some of the DR4⁺ patients and controls.

In diabetics who type as DR4, the positive associations between diabetes and certain RFLPs compared with those of control subjects are as follows: DX α U, 92% versus 46%; DQB β Ω , 81%, 46%; DQ β T6, 81%, 24%; and Bw62, 39%,

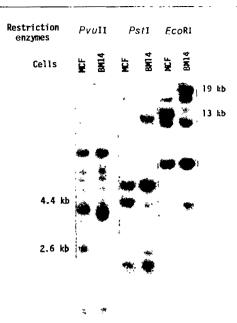

Fig. 2 DNA from HTCs BM14 and MCF (DR4, Dw4) hybridized with a $DQ\beta$ probe. The figure shows the distinguishing features between the $DQ\beta\Omega$ pattern (BM14) and the DQ $\beta\phi$ pattern (MCF). EcoR1 digestion gives a 19-kb (Ω) and a 13-kb (ϕ) band, PstI a 12-kb (Ω) and a 44-kb (ϕ) band. and with Poull a 2.6-kb band is present in the ϕ pattern and absent in the Ω pattern. When DNA from DR4 individuals is digested with Pst1, the 12 5and 4.4-kb bands are used to distinguish Ω from ϕ . However, other DR types also give one or other of these bands; for example, DR1 has a 4 4-kb band, DR2 and DR6 give a 12.5-kb band. It is therefore possible to designate the DR4 to Ω or ϕ by eliminating a band associated with the other haploty pe For example, a DR1, DR4 patient displayed both the 12.5 and 4 4-kb bands By eliminating the 4.4-kb band associated with the DR1 it is possible to assign the DR4 to the Ω type. On this basis all individuals with DR1, DR2 or DR6 showing both bands were classified as Ω or & There was one DR4, DR7 patient and two controls not classified due to clear polymorphism in the DR7. Also amongst the controls was one DR4, DR11 which was not classified due to insufficient data on this group, and a DR3, DR4 due to possible polymorphism here also.

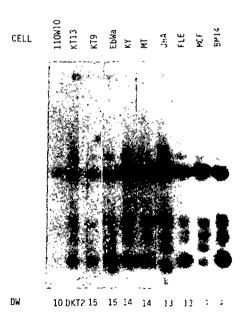

Fig. 3 DNA from HTCs BM14 and MCF (DR4, Dw4) hybridized with a DQ β probe. The distinguishing features between IOQ β Ω and ϕ patterns with Taq1 are 2.0-, 2.3- and 2.5-kb bands with Ω (BM14) and 1.8-, 1.95., 2.2-, 2.4- and 2.6-kb bands with the ϕ (MCF) pattern. Note that the 6-kb band is present in all the DR4 cell lines. All cells give the Ω pattern except for MCF and JHA.

Table 2 Frequencies in DR4⁺ controls, RA and IDDM patients, of DX α and DQ β RFLPs, TA10 and HLA-Bw62 and HLA-B44

RFLP	Controls (%)	RA patients (%)	IDDM patients (%)
DXαU	13/28 (46.4)	15/29 (51.7)	47/51 (92.2)
DXαL	21/28 (75.0)	21/29 (72.4)	24/51% (47.1)
$DQ\beta\Omega^*$	12/26 (46.1)	1	29/36 (80.5)
$DQB\Omega \uparrow$	6/24 (25.0)	16/30 (53.0)§	, , , , , ,
DQβφ*	21/26 (80.8)		12/27# (44.0)
$DQB\Omega t$	19/24 (79.0)	18/30 (60.0)	,,
$DQ\beta\phi T6$	7/29 (24.1)	18/34§ (52.9)	29/36 (80.5)
Serological specificities			
TA10‡	10/24 (41.7)	13/27 (48.1)	4/15 (26.7)
Bw62	5/30 (16.7)	10/32 (31.2)	18/46¶ (39.1)
B44	13/30 (43.3)	13/32 (40.6)	8/469 (17.4)

Significance of differences in frequencies was tested by Haldane's modification²⁸ of Woolf's method²⁹. P values are not corrected for the number of tests.

17%; while negative ones are with DX α L, 47% versus 75%; DQ $\beta\phi$, 44%, 81%; B44, 17%, 43%; and TA10, 27%, 42%. In DR3⁺ diabetics there is also a strong association with DX α U (Table 2).

In rheumatoid arthritis patients, there were no significant differences in the DX α U and DX α L frequencies in DR4⁺ patients and control subjects, although associations were found with DQ $\beta\Omega$ (53% compared with 25%), DQ β T6 (53%, 24%) and Bw62 (31%, 17%) (Table 2).

We next investigated HLA haplotypes that might be potential disease markers by testing the associations between the newly described RFLPs, the serologically detectable DQ-like determinant TA10 and established antigens of the DR, DQ, Dw and HLA-B segregant series in the IDDM and RA patients. Although additional DR4⁻ IDDM patients and controls were used in this analysis, the total control group does not constitute a random panel, having a preponderance of DR3⁺ and DR4⁺ individuals. The significant associations (Table 3) are DX α U with DQ β α , DX α L with DQ β α , TA10 with DQ β α and TA10 with B44; DX α U with DR3; DQ β T6 with DR4 and DQ β T6 with DR1. However, the significance of these associations varied in the three groups tested (control subjects, RA and IDDM patients). The constructs of the three PAAs are based on the significant associations indicated above and shown in Table 2; they are:

```
PAA 1. DX\alpha U \cdots DQB\Omega \cdots
```

The DX α U/DQ $\beta\Omega$ or DX α L/DQ $\beta\phi$ association was present in all the HTCs except EbWa, Dw15 (Table 1).

Our main aim was to try to identify specific molecules or haplotypes likely to be directly involved in the pathogenesis of RA and IDDM. The striking association (>92%) of DX α U with IDDM may be attributable to the high prevalence of the combinations of PAA 1 and PAA 2 which have previously been marked by DR3 and DR4 antigens, both of which are associated with $DX\alpha U$ and are present at a high frequency in $IDDM^{32}$. It is already known that individuals heterozygous for DR3 and DR4 run a higher risk of developing IDDM than do those who are either DR3 or DR4 homozygous¹⁹. The DX α U allele in itself may thus be a risk factor for IDDM. Our studies also indicate that the Bw62/DR4 haplotype is important in both IDDM and RA. The RA patients used in our study did not show as marked an increase in the DQ $\beta\Omega$ component that is part of PAA 2 as did the controls, even though increased frequencies of the Bw62/DR4 haplotype have been reported in RA patients with severe disease^{20,21}. Our RA patients, although fulfilling the clinical criteria for RA, were not selected for severe

P values were computed using Fisher's exact test.

disease, and greater increases in $DQ\beta\Omega$ and $DX\alpha U$ might thus be expected in patients with severe disease. There was no difference in the frequency of TA10 in the RA patients compared with the controls, but its frequency was reduced in IDDM patients, as found by Tait et al.²².

We have also found an increase in the frequency of $DQ\beta\Omega$ in IDDM patients. However, Cohen-Haguenauer et al. 18 reported that, compared with DR-matched controls, IDDM patients showed a decrease in a TaqI, $DQ\beta$, 2.1-kb fragment, which may correspond to our $DQ\beta\Omega$ pattern in PAA 2. This difference may be due to heterogeneity between the populations studied.

The increase in the frequency of the DQ β T6 RFLP in the RA and IDDM patients seems to be a novel finding, whereas the increases in DX α U and DQ $\beta\Omega$ in the IDDM patients represent extensions of known susceptibility axes. In IDDM patients the $DQ\beta T6$ fragment is found at a very high frequency, together with DR4 and DQ $\beta\Omega$ (Table 3); these associations are not apparent in the controls and hence it is not certain whether they represent true associations or combined increases of separate elements in the IDDM patients. The DQ β T6 RFLP does not show preferential association with Bw62 in the DR4⁺ IDDM patients (7/8 of the Bw62⁺ patients and 15/19 of the Bw62⁻ patients have the DQ β T6 fragment). As the frequency of the DQ\beta T6 RFLP is also increased in the RA patients compared with the controls, it could be a new common susceptibility marker in these disorders. Our data also indicate a highly significant association between DQ β T6 and DR1, especially in RA. patients (Table 3); this may have some bearing on the reported increased frequency of DR1 in British²³, Indian²⁴ and Jewish²⁵ RA patients. Interestingly 'MC1', a specificity common to DR1 and DR4, has been described²⁶ and a monoclonal antibody recognizing this specificity has been produced which reacts with cells from more than 90% of RA patients (R. Winchester, personal communication).

Although it is not known whether the $DX\alpha U$ and L, $DQ\beta\Omega$ and ϕ $DB\beta T6$ fragments encode functional HLA class II molecules, we can postulate that these RFLPs may encode class II molecules associated with the pathogenesis of IDDM and RA. Alternatively, they may be in linkage disequilibrium with

^{*} Assignments of DQ β in IDDM patients and control subjects were based solely on TaqI RFLPs, that is, 2 kb for Ω and 1.9 kb for ϕ .

some other, more relevant, genes in the PAAs concerned. We consider that there is not a single gene and/or gene product of each of the PAAs involved, but that several different genes or molecules, possessing complementary functions with hierarchical as well as additive effects, are implicated. Hybrid DQ molecules²⁷, trans combinations of DQ α chains from one PAA and DQB chains from another PAA, may also be relevant, particularly with regard to IDDM susceptibility. These findings provide a basis for investigating the putative HLA class II molecules potentially encoded by genes associated with the DO RFLPs described here.

We thank Dr P. Petersen (DNA probes), Drs G. B. Ferrara, B. Dupont, H. Bashir and N. Kashiwagi (homozygous typing cells) and Dr H. Maeda (monoclonal antibody) for reagents used in this study. Patient material was provided by Professor H. Currey and Dr J. P. Monson of the London Hospital. Financial support was provided by the Arthritis and Rheumatism Council (S.C., W.O.), the Multiple Sclerosis Society (J.A., A.V.G.), MRC (H.F.) and the Wellcome Trust (J.A.S., P.C.). We thank Joanna Lee for help in the preparation of this manuscript.

Polymorphism of human Ia antigens: gene conversion between two DR β loci results in a new HLA-D/DR specificity

Jack Gorski & Bernard Mach

Department of Microbiology, University of Geneva Medical School, 1211 Geneva 4, Switzerland

The polymorphic HLA-DR β -chains are encoded within the human major histocompatibility complex (MHC) by multiple loci resulting from gene duplications. Certain DR haplotypes can be grouped into families based on shared structural factors. We have studied the molecular basis of HLA-DR polymorphism within such a group which includes the haplotypes DR3, DR5 and DRw6. Molecular mapping of the DR β -chain region allows true allelic comparisons of the two expressed DR β -chain loci, $DR\beta I$ and $DR\beta III$. At the more polymorphic locus, $DR\beta I$, the allelic differences are clustered and may result from gene conversion events over very short distances. The gene encoding the HLA-DR3/Dw3 specificity has been generated by a gene conversion involving the $DR\beta I$ and the DRBIII loci of the HLA-DRw6/Dw18 haplotype, as recipient and donor gene, respectively. Based on which allele is found at DRBIII, the less polymorphic locus, two groups of haplotypes can be defined: DRw52a and DRw52b. The generation of HLA-DR polymorphism within the DRw52 supertypic group can thus be accounted for by a succession of gene duplication, divergence and gene conversion.

The polymorphism of class II molecules is responsible for the restriction of T-cell activation by antigen-presenting cells. The polymorphic regions of the class II molecules are therefore implicated in interactions with both the T-cell receptor and with antigen. Since some alleles are more efficient at presenting certain antigens than others, class II genes are also referred to as immune response genes (reviewed in refs 1 and 2). The class II products of the human MHC (the HLA complex) include the HLA-DR, DQ and DP antigens³. HLA-DR molecules are the predominant class II products on the cell surface, and the polymorphism is associated with the β -chain. The polymorphic regions of the DR β -chains are located predominantly at the N-terminal of the mature polypeptide chain⁴, corresponding to the first structural domain. The DR subregion contains multiple highly homologous β -chain loci⁵⁻⁷ but only one α -chain

locus ⁸⁻¹⁰. In the DR3 and DRw6 haplotypes, the three β -chain loci have been linked on a molecular map¹¹. The DRβII locus is a pseudogene without a first domain exon and the two expressed loci, βI and βIII , are the result of a recent duplication11.

The serologically identified DR specificities can be grouped on the basis of their reactivity with supertypic sera¹². The haplotypes within such a supertypic group have similar Southern blot patterns^{13,14} and, within the supertypic group DRw52, restriction maps of genomic clones are very similar¹¹. This implies a common evolutionary origin of the haplotypes within a supertypic group. Based on the structural similarity of the HLA-DR β -chain region of these haplotypes, individual DR B-chain genes can now be assigned to specific loci and true allelic comparisons made.

The nucleotide sequences of the polymorphic first domains of the two active loci (βI and βIII) of the DR3, DRw6a and DRw6b haplotypes were determined. The sequence of a DR5 βI locus¹⁵ is added to the comparison. The allelic sequences for each locus (Fig. 1a and b) are presented in relation to a consensus sequence. It is evident that locus $DR\beta I$ (a) is more polymorphic than $DR\beta III$ (b) as all the $DR\beta I$ sequences are different. Within the locus $DR\beta I$ there is a clearcut clustering of the nucleotide differences around position 185-205 (the 'hypervariable region'). This is in contrast with DR β -chain sequence comparisons made in a nonallelic manner and across supertypic groups, where a different pattern of variation is observed. This can be seen when the consensus sequences of the two loci are compared (Fig. 1c). An additional region of variability is seen from base pair (bp) 15 to 22.

The nature of the polymorphic differences at the βI locus was explored in detail. It was observed that the sequence of the DR\$I locus of HLA-DR3 can be generated by exchanging two short segments of DNA from the βI and the βIII loci of the haplotype DRw6a (Fig. 2a). Given the phenomenon of positive interference for multiple double recombination events, it is more likely that a single gene conversion with interrupted repair¹⁶ accounts for the structure of the DR3 BI locus. A schema of the conversion event is shown in Fig. 2b, where the DRw6a βIII locus acts as donor and the DRw6a BI locus as recipient, resulting in the sequence of the DR3 gene. As expected with such a mechanism, the βIII locus of HLA-DR3 is identical to that of HLA-DRw6a.

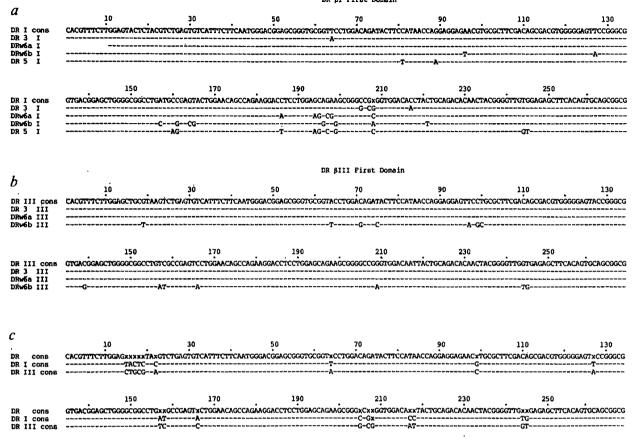

Fig. 1 Sequence of the DR β-chain first domain of the DR3 haplotype, two DRw6 haplotypes and a published DR5 haplotype¹⁵. a, βI locus; b, βIII locus. The consensus sequence (cons) is the base found at that position in at least two of the sequences. c, Comparison of locus I and locus III sequence differences by aligning the consensus sequences for each locus and deriving a DRβ consensus. Regions where βI and βIII differ from each other and which may influence locus-specific conformation of the protein product are easily visualized.

Methods. Sequences were obtained from subclones of the first domain exon of previously described cosmid and phage genomic clones^{6,11}, by both the chemical²³ and dideoxy²⁴ methods, as well as from cDNA clones⁵. DR3 sequences are from a cosmid library of the consanguineous typing cell line AVL; DRw6a sequences are derived from a cosmid library and cDNA library of the consanguinous homozygous typing cell line HHK; DRw6b sequences are from a Charon 30 phage library of a DR4, DRw6 line. The DRw6 genes were identified by Southern blot comparisons with DRw6 and DR4 genomic DNAs (see ref. 25 for an example). The cDNA-derived sequence of DRw6b βIII⁵ as well as a phage-derived sequence²⁵ have been published previously.

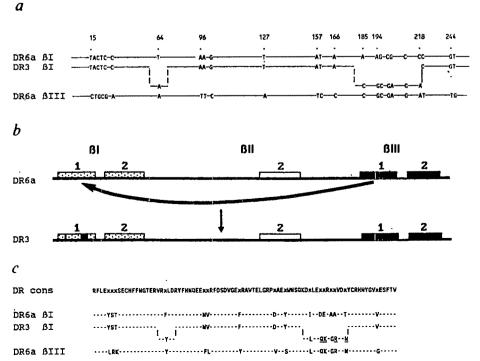

Fig. 2 Intrachromosomal gene conversion between two DRw6 β-chain loci genes. a, The first-domain sequences of the two DR6a loci are aligned with the sequence of the DR3 βI locus. A solid line indicates identical sequences. Relevant nucleotide positions are shown to facilitate comparison with the sequence in Fig. 1. Because of the uncertainty in the limits of the conversion event, dotted lines are used to indicate cross-over points. b, Schematic representation of genes participating in the conversion event; c, aminoacid sequence of the first domains of the DR3 β I and DRw6a β I and β III chains showing the block of amino acids transferred by the conversion event. Non-conservative aminoacid changes in the DR3 BI chain are underlined. The consensus approach is used to aid visualization of amino-acid differences between the βI and βIII loci. The block of amino acids transferred must interact with these differences in the generation of the novel epitope.

The replacement of this short segment of DNA of the DRw6 βI locus (Fig. 2) has given rise to a gene encoding a different serological and T-cell specificity. The B-cell lines AVL (DR3, 3) and HHK (DRw6, w6), from which these genes have been cloned, have distinct serological reactivities, and alloreactive T-cell proliferation assays distinguish these lines as Dw3 and Dw18, respectively¹⁷. The transfer of the block of amino acids from the DR β III-chain to the DR β I-chain (Fig. 2c) results in the loss of two negatively charged amino acids and a gain of two positively charged residues. The introduction of this region into the context of the βI locus must result in a novel conformation which gives rise to the DR3/Dw3 specificity. DR3 is a common haplotype which is associated with an increased risk for certain diseases.

Upon further analysis of the highly polymorphic region of the $DR\beta I$ locus, an example of a possible interchromosomal

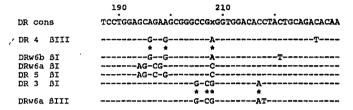

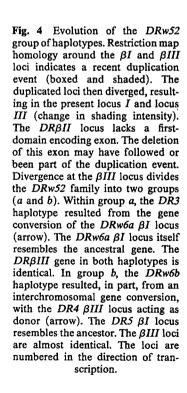

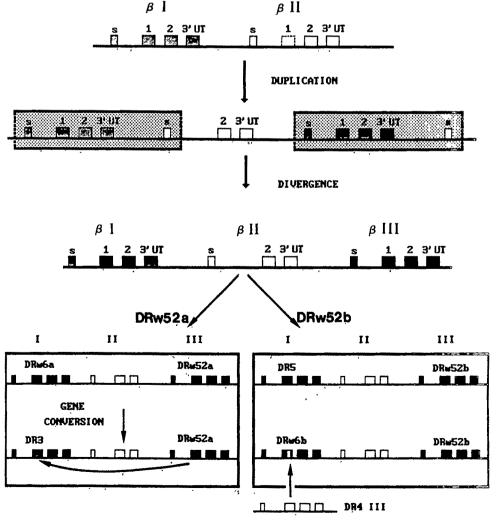

Fig. 3 An example of a possible interchromosomal gene conversion between distantly related haplotypes. The asterisks mark positions common to the DR6b βI- and DR4 βIII-chains. The DR3 conversion event is also marked. The DR4 βIII sequence is derived from a Charon 30 phage library of the DR4, DRw6 cell line mentioned previously.

gene conversion event was observed (Fig. 3). This region, which is similar in $DRw6a\ \beta I$ and $DR5\ \beta I$, is very different in the βI locus of DRw6b. Surprisingly, it is identical to the same region in the βIII locus of DR4, a haplotype from a distantly related supertypic group, DRw53. It is thus likely that the $DRw6b\ \beta I$ locus has resulted from a gene conversion between an ancestral gene similar to $DRw6b\ \beta I$ as recipient and the βIII locus of the DR4 haplotype which acted as donor.

This region of high allelic polymorphism, where we observe examples of gene conversion, is the same as that involved in the I-E to I-A conversion event giving rise to the $I-A^{bm12}$ mutation in mice¹⁸⁻²⁰. Furthermore, a micropolymorphism reported in the DR4 haplotype in this same DNA segment²¹, correlating with changes in alloreactive T-cell recognition, can be attributed to a gene conversion of the DR4 βII locus, with the DR4 βIII locus acting as donor. An interesting observation is that in all these cases the donor locus is 3' of the target locus with respect to the direction of transcription. Together, these results suggest a conversion hotspot responsible for this hypervariable region. The presence of this hotspot implies either that conversion occurs here preferentially for physical reasons or that conversion is random but selection has favoured those events occurring in this region.

Concerning the less polymorphic $DR\beta III$ locus, nucleotide sequence comparison defines two groups of haplotypes, DRw52a and DRw52b, whose $DR\beta III$ loci differ by 11 bp. The first group, DRw52a, includes some DR3 and some DRw6 haplotypes (Fig. 1b). The second group, DRw52b, includes other DR3 and DRw6 haplotypes (Fig. 1b and unpublished results) as well as DR5 (B. Schwartz, personal communication). Hybridization with appropriately chosen oligonucleotides has

allowed us to type unknown individuals as DRw52a or DRw52b (ref. 22 and unpublished) in a sizeable number of normal and diseased individuals. This form of analysis can be of considerable use in phylogenetic studies of human populations.

Taken together, these results can account for the evolution of the DR genes in the DRw52 supertypic group (Fig. 4). The ancestral features of this family are the relatively recent duplication of the βI locus and the silencing of the βII locus by deletion of the first domain encoding exon¹¹. The duplicated $DR\beta I$ loci then diverged into βI and βIII . Further divergence resulted in a branching into two lineages (DRw52a and DRw52b) based on common alleles at the less polymorphic locus, DRβIII. In the DRw52a group, the DRw6a haplotype gave rise to the DR3 specificity by the gene conversion described here. The DRw6b haplotype was probably involved in an interchromosomal gene conversion with the DR4 BIII locus acting as donor.

This analysis provides a framework for assigning serological specificities to the products of the different loci of the DRw52 haplotypes. Allelic differences in the product of the DR\$III locus split DRw52 into a and b. It has already been shown that this locus encodes the DRw52 specificity for the case of the DRw6b haplotype²⁵. We propose that the distinct epitopes DRw52a and DRw52b (Fig. 4) will correspond to serological and T-cell specificities. In addition to the product of locus DRBIII, each haplotype obviously also expresses the product of their βI locus, which determines the fine DR specificity.

The data described here represent an example of relatively rapid evolution of a multigene family in which the loci appear to diverge at different rates following a duplication event. The time of divergence may be estimated by analysing this group of haplotypes in other geographical (non-European) groups whose migratory patterns are known.

The divergence in this gene family is generated in part by gene conversion. Since this mechanism can involve the transfer of preselected epitopes, the resulting additional polymorphism is frequently maintained in the population. Therefore, even if gene conversion is a relatively rare event, it can play a major role in the generation of polymorphism by producing functionally effective variants. It is generally thought that this polymorphism confers a selective advantage to a population in terms of its ability to cope with various pathogens. A genetic system with multiple loci undergoing conversion events could regenerate polymorphism in populations which have undergone bottlenecks due to migration or adverse environmental factors.

We thank Chantal Mattmann and Madeleine Zufferey for technical assistance, Dr B. Schwartz for providing sequence data for DR5 prior to publication and Dr J. J. van Rood for comments on the manuscript. This work was supported by a grant from the Swiss National Fund for Scientific Research.

Note added in proof: From a recent analysis of micropolymorphism of HLA-DR4 (ref. 26), we propose that one DR4βI allele, Dw10, has arisen by a gene conversion, with DRw6aβI acting as donor.

Hepatitis B virus DNA integration in a sequence homologous to v-erb-A and steroid receptor genes in a hepatocellular carcinoma

Anne Dejean*, Lydie Bougueleret†, Karl-Heinz Grzeschik‡ & Pierre Tiollais*

‡ Institut für Humangenetik der Westfalischen Wilhems-Universität, 4400 Munster, FRG

Hepatitis B virus (HBV) is clearly involved in the aetiology of human hepatocellular carcinoma (HCC)1 and the finding of HBV DNA integration into human liver DNA in almost all HCCs studied²⁻⁷ suggested that these integrated viral sequences may be involved in liver oncogenesis. Several HBV integrations in different HCCs^{8,9} and HCC-derived cell lines¹⁰⁻¹⁴ have been analysed after molecular cloning without revealing any obvious role for HBV. From a comparison of a HBV integration site present in a particular HCC8 with the corresponding unoccupied site in the nontumorous tissue of the same liver, we now report that HBV integration places the viral sequence next to a liver cell sequence which bears a striking resemblance to both an oncogene (v-erb-A) and the supposed DNA-binding domain of the human glucocorticoid receptor and human oestrogen receptor genes. We suggest that this gene, usually silent or transcribed at a very low level in normal hepatocytes, becomes inappropriately expressed as a consequence of HBV integration, thus contributing to the cell transformation.

We have previously reported the molecular cloning of the single integrated viral sequence present in the liver tumorous nodule of patient D and we have determined the sequences of the cellular-viral junctions8. The viral insertion was a continuous subgenomic fragment 1.4 kilobases (kb) long (Fig. 1a) containing the cohesive-end region, gene C and the beginning of gene pre-S1. We therefore used the 1.1-kb and 5.8-kb HindIII cellular fragments and the 1.8-kb EcoRI host-viral fragment (respectively referred to as LT (left tumour), RT (right tumour) and MT (medium tumour); Fig. 1a) to isolate the unoccupied site from a λ phage library of DNA extracted from the non-tumorous liver of patient D. This part of the liver did not seem to contain any integrated HBV sequences. Seven overlapping clones, hybridizing to one and/or the other of the three probes, were isolated and represented 32 kb of cellular DNA at the unoccupied site (Fig. 1b). Southern blots of restriction digests of the seven clones using total human DNA as a probe showed that the host sequence at the viral insertion site corresponds mainly to unique sequence DNA (Fig. 1a, b, solid bars). Comparison between the restriction maps of the unoccupied site (Fig. 1b) and the integrated site (Fig. 1a) did not reveal any major genomic rearrangements in the cellular DNA. Integration took place within a small EcoRI fragment of 400 base pairs (bp) which we subcloned and refer to as MNT (medium non-tumour)

To investigate whether HBV became integrated in the vicinity of a cellular gene in the human genome, we determined the nucleotide sequence¹⁵ of the normal allele. This sequence

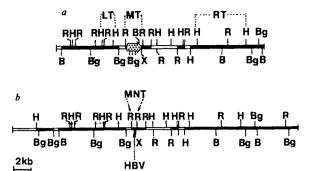

Fig. 1 a. Restriction map of the occupied site. This has previously been isolated from a library of cellular DNA extracted from the tumorous part of the liver of patient D8. The stippled region represents the 1.4-kb integrated HBV sequence. The arrowhead denotes the same orientation as the viral (+)strand30. Solid bars denote unique sequences and open bars regions containing repetitive cellular sequences. Restriction sites are: R, EcoRI; B, BamHI; Bg, Bg/II; H, HindIII; X, XhoI. The cloned 1.1-kb HindIII, 1.8-kb EcoRI and 5.8-kb HindIII cellular fragments are referred to as LT, MT and RT. b, Restriction map of the unoccupied site. The cloning experiment in which partial MboI digests of cellular DNA were cloned into λ L47.1 was as described previously¹¹. A library, made with cellular DNA from the non-tumorous part of the liver of patient D, was screened with LT, MT and RT as probes. Seven positive overlapping clones were analysed, representing 32 kb of cellular DNA. The cloned 400-bp EcoRI cellular fragment is referred to as MNT. The site of HBV integration within MNT is indicated by an arrow.

revealed the presence of an open reading frame (ORF) of 519 nucleotides which was interrupted in the middle by the viral insertion (Fig. 2). Since methionine codons were present only at the 3' end of the ORF, this region can only correspond to a single exon from a split gene. Two acceptor-like (A-L1, A-L2) and two donor-like (D-L1, D-L2) consensus sequences of splice junctions¹⁶ could be localized, respectively, at the 5' end and the 3' end of the ORF (Fig. 2). A computer-assisted analysis 17 showed that the region between A-L2 and D-L1 had a strong probability of being an exon. A search for related sequences in the NBRF protein data bank¹⁸ identified a remarkable homology (22 identities out of 49) between the translation product of the exon-like region of the ORF (amino-acid residues 69-117) and the amino-terminal region of the v-erb-A oncogene product (residues 8-58)19 (Fig. 3). Moreover, a significant homology has recently been reported between the v-erb-A protein and either the human glucocorticoid receptor (hGR)²⁰ or the human oestrogen receptor (ER)21. The alignment of the amino-acid sequence of hGR and ER with the exon-like protein product showed, in both cases, 19 identities out of 49 (Fig. 3). As already observed for v-erb-A, hGR²⁰ and ER²¹, the identity became greater beyond amino acid 96 of the ORF, which corresponds to a cysteine-rich region. In particular, the four cysteines conserved between v-erb-A, hGR and ER are present at the same position in the ORF. Although the homology continues for v-erb-A, hGR and ER-all derived from cDNA clones-no significant homology was found beyond residue 117 for the ORF. However, since the D-L1 sequence (next to residue 117) is strictly identical to the consensus sequence of a donor site, it could thus correspond to an exon/intron boundary.

The integration of HBV sequences interrupted the cellular open reading frame and generated a microdeletion of 7-12 bp (boxed in Fig. 4). This minor rearrangement provides evidence that the situation we are studying in patient D is probably very near the initial integration event. In addition to the microdeletion, the viral integration—interrupting the cellular ORF—generated a new viral-host hybrid sequence such that the first 29 codons of the viral pre-S1 gene became fused and in phase with the last 28 codons of the cellular exon (Fig. 4). Remarkably,

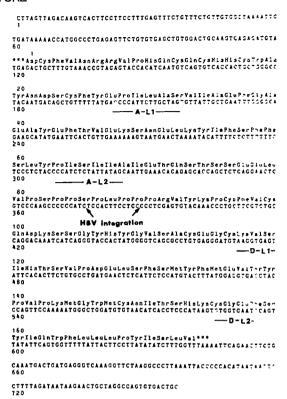

Fig. 2 Nucleotide sequence of the unoccupied site. Nucleotides are numbered at the left side. The deduced amino-acid sequence of the 519-bp open reading frame is shown above the nucleotide sequence. The amino-acid sequence is numbered from the first codon of the ORF. A large number of splice junction sequences have been reported¹⁶. The compilation of the data supports the consensus (C)₁N_TAG/G for acceptors and the consensus AG/GTAGT for donors. The two acceptor-like (A-L1 and A-L2) and donor-like (D-L1 and D-L2) sequences are underlined. The site of HBV integration in the middle of ORF is indicated by an arrow. The cloned 3.4-kb HindIII fragment, encompassing the unintegrated site in the normal allele, was sonicated, treated with the Klenow fragment of DNA polymerase plus deoxyribonucleotides (2 h, 15 °C) and fractionated by agarose gel electrophoresis. Fragments of 400-700 bp were excised and electroeluted. DNA was ethanol-precipitated, ligated to dephosphorylated Smalcleaved M13 mp8 replication form DNA and transfected into Escherichia coli strain TG-1 by the high-efficiency technique of Hanahan³¹. Recombinant clones were detected by plaque hybridization using the MNT (Fig. 1b) subclone DNA as a probe. Singlestranded templates were prepared from plaques exhibiting positive hybridization signals and were sequenced by the dideoxy chain termination procedure15 using buffer gradient gels3

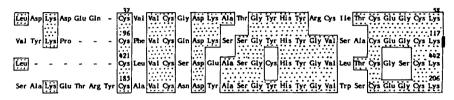

the viral genome became integrated a few nucleotides upstream from the most conserved Cys-rich portion of the ORF (Fig. 3), maintaining the integrity of this region.

Using a panel of 17 mouse-human and Chinese hamster-human somatic cell hybrid DNAs^{22,23}, we localized the ORF to chromosome 3 (data not shown), while the c-erb-A oncogene²⁴, hGR²⁵ and ER²⁶ have been mapped, respectively, to human chromosomes 17, 5 and 6. In preliminary experiments, we hybridized the MNT probe, encompassing the exon-like region of ORF, to a Northern blot of polyadenylated RNAs extracted from five human livers, but found no detectable transcripts. A large number of human fetal and adult tissues will have to be tested similarly to reveal any active transcription of this region.

The conserved Cys-rich region which extends over 60 aminoacid residues in v-erb-A protein, hGR and ER is thought to include the DNA-binding domain of the molecule^{20,21}. We can thus speculate that the corresponding homologous region of ORF, truncated by the exon-intron boundary, is part of a cellular gene that shares a common functional domain with hGR, ER

Fig. 3 Amino-acid sequence alignment of the v-erb-A oncogene protein19, the translation product of the exon-like region of ORF, the human glucocorticoid receptor (hGR)²⁰ and the oestrogen receptor (ER)²¹. The limits of the exon-like region of ORF, defined by A-L2 and D-L1 boundaries, are indicated by rectangles. To predict the location of exon-like regions, we used the discriminating program PREDICTOR¹⁷ Two subsets of the GenBank data library, containing either only exon or only intron sequences, were taken as reference pool. The program PROBE3-EXPLOR3 (ref. 18), allowing the search for ambiguous nucleic or peptidic patterns, was used to screen both the NBRF (proteins) and the GenBank (DNA) data banks. These programs were run on a MV8000 32-bit minicomputer. Amino-acid residues 69-117 from the ORF were aligned with amino-acid residues 8-58 from p75gag-erb-A, residues 397-442 from

and v-erb-A gene products and which could exert a transcriptional regulatory function on specific genes.

Although the way in which HBV participates in the formation of a liver cancer is unknown, the experiments reported here could promote our understanding of one possible mechanism of HBV carcinogenesis. In patient D the viral integration, interrupting the exon-like region (Fig. 2), created a chimaeric viralhost open reading frame (Fig. 4). The HBV insertion took place a few nucleotides upstream from the beginning of the putative DNA-binding domain. Since a viral promoter has been defined by in vitro transcription approximately 30 nucleotides upstream from the initiator codon of the pre-S1 gene²⁷, we suggest that, in the tumorous part of the liver, a readthrough transcription occurred from the viral promoter. Although protein or RNA from the tumour is no longer available to test this hypothesis, it is most probable that inappropriate activation of the putative gene as a consequence of HBV integration resulted in expression of a truncated protein at greater levels than that of the native protein. This protein could participate directly in the subsequent cell transformation.

Several arguments suggest that hormonal factors are involved in human hepatocarcinogenesis. The incidence of HCC is threeto sixfold greater in males¹, and the use of oral contraceptives in females is associated with the development of hepatic adenoma²⁸. Moreover, the ability of oestrogenic hormones to function as promoters of neoplastic development in rat liver has been clearly demonstrated²⁹. The finding that HBV sequences have become integrated into a putative cellular gene sharing homology with the steroid receptor genes is therefore intriguing and suggests that, in some cases, hormonal and HBV carcinogenesis may be directly related.

Fig. 4 DNA sequences at the HBV integration site. The sequences of the left and right host-viral DNA junctions at the occupied site (upper sequence) are compared with the human DNA sequence at the unoccupied site (lower sequence). The bold-face letters indicate the viral sequence. Nucleotides of the ORF and the HBV genome³³ are numbered. Homologous nucleotides between the two sequences are indicated by sloping lines. The 7-bp CACTTCC present in the normal allele and deleted after the viral integration in the occupied site is boxed. Because HBV DNA and cellular DNA shared a 2-bp and 3-bp sequence homology at a point coincident, respectively, with the left and right host-viral junctions (dashed lines), the deleted fragment could be up to 12 bp long. The DR2 copy of the 11-bp viral direct repeat specifically involved in HBV integration⁸ is indicated. The putative chimaeric protein, generated by the HBV inversion, between the first 29 amino acids of the viral pre-S1 gene product and the last 28 amino acids of the cellular exon protein product is partially represented at the fusion

Analysis of deletions in DNA from patients with Becker and Duchenne muscular dystrophy

Louis M. Kunkel and co-authors*

Division of Genetics, The Children's Hospital, Boston, Massachusetts 02115, USA

Duchenne muscular dystrophy (DMD) is an X-linked recessive genetic disorder for which the biochemical defect is as yet unknown. Recently, two cloned segments of human X-chromosome DNA have been described which detect structural alterations within or near the genetic locus responsible for the disorder^{1,2}. Both of these cloned segments were described as tightly linked to the locus and were capable of detecting deletions in the DNA of boys affected with DMD. In an attempt to determine more precisely the occurrence of these deletions within a large population of DMD patients and the accuracy of one of the segments, DXS164 (pERT87), in determining the inheritance of the DMD X chromosome, the subclones 1, 8 and 15 were made available to many investigators throughout the world. Here we describe the combined results of more than 20 research laboratories with respect to the occurrence of deletions at the DXS164 locus in DNA samples isolated from patients with DMD and Becker muscular dystrophy (BMD). The results indicate that the DXS164 locus apparently recombines with DMD 5% of the time, but is probably located between independent sites of mutation which yield DMD. The breakpoints of some deletions are delineated within the DXS164 locus, and it is evident that the deletions at the DMD locus are frequent and extremely large.

The previously described deletions of the DXS164 region and the XJ-1.1 junction clone^{1,2} were assumed to be large, for neither set of cloned segments exhibits any common sequence overlap and yet both cloned segments are absent from most of the same deletion DNA samples². To increase the possibility that a particular deletion would exhibit a break within cloned DNA, the DXS164 region was expanded further by chromosome walking³ in human genomic libraries constructed in the phage vector EMBL-3 (ref. 4). Following five bidirectional walks, a 137kilobase (kb) contiguous stretch of DNA was obtained from the DXS164 region. All DNA segments obtained from the 137 kb of DNA were subcloned in plasmid vectors and segments of unique sequence were identified for the entire length. The two previously described subclones (pERT87-1 and -8; ref. 1) and a new unique-sequence segment (pERT87-15) which also detects restriction fragment length polymorphisms (RFLPs; ref. 5) were sent to other investigators interested in DMD.

The three DXS164 subclones, which are spaced over a 50-kb

section, were tested for deletion by hybridization against the DNA isolated from males exhibiting the DMD and BMD phenotype. The results of this analysis for 1,346 males are presented in Table 1. As the results were obtained in many different laboratories, they are presented separately for each laboratory. Of all DMD and BMD males tested, 6.5% show deletions at the DXS164 locus, a slightly lower percentage than that found previously1. A difference was observed in the incidence of deletions between DMD males with a clear family history of the disease (8.3%) and those with no family history (5.8%). Such a difference might be a reflection of the incidence of deletion mutation in maternal and paternal meiosis. Any true sporadic case of DMD where the mother is not a carrier of the disease represents a mutation which must occur only in female meiosis with no paternal contribution. Familial cases would be assumed to have a contribution of both male and female meiotic deletion events. Thus, if the frequency of deletion mutations at the DMD locus were nearly equal in males and females, one might assume that a higher incidence of deletions, as presented in Table 1, would be observed in familial cases. Prediction of affected individuals in families segregating a deletion which is assumed to be the primary genetic cause of the disease (of more than 150 normal boys, no deletions were observed) should be highly accurate.

As indicated in Table 1, two boys with BMD were found to have a deletion of the DXS164 region. Linkage analysis has shown that the locus for BMD is localized near, or is a potential allele of, DMD⁶⁻⁹. The finding of deletions in the DNAs of BMD males which overlap with deletions found in DMD males suggests that if they are two separate loci they are indeed close to one another. Alternatively, if BMD and DMD are caused by different alleles at the same locus, then the milder BMD phenotype might be expected to be the result of a low-level expression of the DMD/BMD gene product. If this were the case, the BMD deletions might not involve DNA sequences that are absolutely necessary for the expression of the DMD/BMD gene product.

The three DNA probes from the DXS164 region that were distributed to other investigators each recognize the informative RFLP alleles given in Table 2. The separate RFLP alleles of pERT87-1 and -8 exhibit a degree of disequilibrium and are only informative in ~60% of women tested, despite there being many different enzyme-defined loci. The three separate loci of pERT87-15 defined by different enzymes, although in some degree of disequilibrium with each other, are closer to equilibrium with the pERT87-1 and -8 loci. When the three enzyme-defined loci of the pERT87-15 probe were used in combination with the BstXI locus of pERT87-8 and the XmnI locus of pERT87-1, 25 of 28 (89%) unrelated women at risk for DMD or BMD were observed to be informative for linkage between one or more of the RFLP-detecting loci and the disease locus.

The DNAs isolated from 1,346 DMD and BMD males from separate kindreds were cleaved with various restriction enzymes. Diagnosis of DMD and/or BMD was established by characteristic history, physical examination, increased CPK levels and, in many cases, a positive muscle biopsy¹⁹⁻²¹. Following separation of digested DNA by electrophoresis, the DNA samples were hybridized²² with one or more of the DXS164 subclones pERT87-1, pERT87-8 and pERT87-15. Not all samples were hybridized with all the subclones, but most were hybridized with pERT87-8. The investigator's laboratory in which the DNA isolations and, in most cases, the hybridizations were accomplished are indicated. The patients were divided into three categories: DMD-F, DMD males from a family in which there was more than one affected individual or, in a few cases, where the mother had an elevated CPK, but no clear family history of DMD; DMD-S, DMD males where there was no family history of the disease and the mother had a normal CPK value; BMD, males who exhibited the less severe X-linked myopathy. The number of boys studied within each of these three categories is shown for each laboratory. Deletions were defined as complete absence of hybridization for a DXS164 subclone and the number of individuals with absent fragments is given in each category. Those DMD males who exhibited deletions were representative of the clinical spectrum for DMD and included males who were mentally retarded as well as those not mentally retarded. Many DMD boys who were diagnosed as mentally retarded did not exhibit a deletion of DXS164 subclones. Those BMD males who exhibited deletion of DXS164 subclones were both on the more severe side of the BMD clinical spectrum, but both were wheelchair-bound later than a typical DMD patient: one was from a familial case of BMD and the other was a sporadic occurrence of BMD. Both are functioning well in their mid-twenties and one male is still able to drive a car.

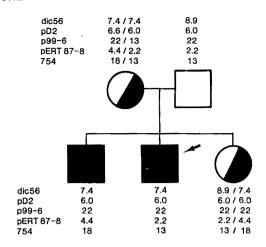

* Most of these DNA samples were obtained from the individual listed and were sent to L.M.K. in Boston, where they were tested for deletion. † Most of these DNA samples were sent to K.E.D. at Oxford, where they were tested for deletion. K.E.D. received other DNA samples from Dr Schwarts (Denmark) and Drs Ch. Coutelle, Spiegler, Herrmann and Szibor (FRG).

Segregation analysis of these RFLP-detecting loci in multiple families at risk for BMD and DMD has shown that recombinants are possible between DXS164 and the disease locus; one such recombinant is shown in Fig. 1. The family consists of two affected sons and a daughter whose level of creatine phosphokinase (CPK) and muscular hypertrophy indicate a carrier status. The boy indicated by an arrow in the figure has clearly received from his mother a 2.2-kb hybridizing BstXI fragment for pERT87-8, whereas his affected brother and carrier sister have each received a 4.4-kb fragment. Thus, the X chromosome of the boy carrying the 2.2-kb fragment must be the result of a recombination event between DXS164 locus and DMD.

To determine more accurately the meiotic exchange points in this family and to minimize the possibility of sample error, the same family was also tested for segregation with other Xp cloned loci. The PstI RFLP detected by the cloned probe 754 (DXS84; ref. 10) also exhibited recombination in the same individual, whereas the other loci, DXS41 (99-6) and DXS43 (D2)^{11,12}, appear to be non-recombinant. This is an unexpected result based on previous notions of gene order for these loci on the

X chromosome $^{10-15}$. Physical mapping of these marker loci using panels of hybrid cells 16,17 containing translocation chromosomes from two independent X; autosome translocations found in females with DMD localize DXS164 (ref. 14), DXS41 and DXS43 (refs 11, 12) on the pter side and DXS84 (refs 13, 17) on the centromere side of the translocation breakpoints. If the translocation exchange points in these two patients are in the DMD gene^{17,18}, the order of these loci would be as presented in Fig. 1 ('old order'). The recombination data of Fig. 1 are inconsistent with this order in this particular family. There must be a recombination event between DMD and DXS84(754), one between DMD and DXS164(pERT87-8), and another between DXS164(pERT87-8) and DXS41(99-6) for this latter marker to appear non-recombinant. The presumed order would require three meiotic exchanges within a region of previously closely linked markers^{9,15}. An alternative, and perhaps more likely explanation is that the DMD mutational site in this family maps between DXS41 and DXS164 and a single recombination (indicated at the bottom of Fig. 1) between DXS164 and the DMD mutation site would explain the results.

Fig. 1 Segregation of five Xp cloned loci in a DMD family. O, Females; □, males; ■, DMD-affected individual; ②, DMD carrier. DNA was isolated11 from five members of a DMD kindred. Diagnosis of DMD was established as described in Table 1 legend, and the mother was judged to be a carrier of the disease as she exhibited an increased concentration of CPK^{19,20} and had given birth to two affected individuals. The mother, though, had no knowledge of any other case of DMD in her family. The daughter was judged to be a carrier as she had extremely elevated CPK (relative to other female carriers) and exhibited hypertrophy of the leg muscles, although no weakness. The DNA samples were cleaved with the various restriction enzymes appropriate for each of the cloned DNA probes. Gel electrophoresis, transfer and hybridization were as described previously11. The different loci were tested by hybridization with the following cloned DNA fragments (given from the most distal): DXS143, dic56; DXS43, pD2; DXS41, p99-6; DXS164, pERT87-8; and DXS84, 754 (the most proximal). The various cloned segments had been physically mapped previously 10-14. The numbers above and below each symbol indicate the size of hybridizing restriction fragments (alleles). Segregation of the locus DXS143 (ref. 23) is included to show that the samples from the non-recombinant boy and the father were not inverted. Two possible orders for the loci are indicated at the bottom of the figure; the first places the DMD locus at the point where the translocation breaks occur in two females with DMD; the second order (new order) represents an interpretation of the results obtained in the family study.

In the cases where DXS164 has been observed to recombine with DMD (eight known instances) and where DXS84 was also informative (five instances), both markers were recombinant. These results are consistent with the fact that the mutations giving rise to DMD in some families lie distal to DXS84, two translocation breaks in Xp21 (refs 16, 17) and the DXS164 locus. Thus, DXS164 may lie between these two translocation breaks and additional sites of mutation, all of which yield the phenotype of DMD and/or BMD. Alternative explanations for the linkage results could include a different X-linked locus with a phenotype very similar to DMD or new mutations which would appear as recombinants. Potentially consistent with the latter possibility is the observation that only one of the eight DXS164 recombinants observed occurs in the third generation or thereafter in a multi-generation DMD family.

For whatever reason, the exclusive use of DXS164 cloned probes as linked markers would lead to some mistakes when predicting the inheritance of the DMD X chromosome. This result has major implications for the prediction of the DMD genotype. Although the exact error rate is difficult to calculate (because only recombinants for other closely linked markers were tested for the segregation of DXS164 clones), best estimates can be made from the observation that approximately one-half of DXS84 recombinants (estimated at 10% recombination; ref. 9) are also DXS164 recombinants. This leads to the assumption that DXS164 will be in error in predicting the DMD X chromosome 5% of the time. It is strongly advised that the DXS164 locus be used in combination with other Xp21 flanking markers to construct an Xp21 haplotype. Given that the DXS164 locus seems to be localized between mutations found in different families which yield the DMD phenotype, DXS164 should not be considered as a flanking marker to DMD with other Xp21 loci. In a diagnostic situation, it would be unknown in which direction the particular mutation actually occurred relative to DXS164. Combined multi-locus information should improve the accuracy of genotype prediction in DMD families, assuming, of course, that the observed prediction errors for the DXS164 locus are caused by recombinants and not by new mutations or a different, as yet uncharacterized, locus.

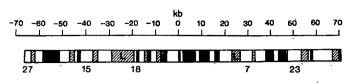

The deletions observed in the DNAs of boys with DMD (and also BMD) provide the means to start to define important

segments of Xp21 which might be involved in the normal functioning of the DMD locus. Therefore, 53 of the 88 DNA samples which constituted deletions for the three DXS164 subclones distributed were tested for the absence or presence of additional subclones from the entire 137 kb of DNA from the DXS164 locus. A representative hybridization analysis is shown in Fig. 2 for five DXS164 subclones hybridized to nine different deletion DNA samples. The subclones are located within the DXS164 locus on either side of pERT87-1 and -8, and the five subclones combined can detect size differences between PstI-hybridizing fragments over 45 kb of the DXS164 locus. Among the nine deletion DNA samples, five showed no DXS164-hybridizing PstI fragment. The remaining four DNA samples exhibited some fragments but not others; these samples thus have breakpoints within the DXS164 locus, and one (Fig. 2, lane 3) of the breakpoints is preliminarily determined as an altered PstI hybridizing fragment. By using additional subclones from the DXS164 locus, each breakpoint can be mapped more precisely to a specific subregion. Once localized to a specific region, the appropriate restriction enzyme can be chosen to best demonstrate the actual breakpoint (within 100-1,000 base pairs (bp)).

Table 2 RFLP-detecting subclones of DX3164

	Insert size		Allele (k		Allele frequency		
Subclone	(kb)	Enzyme	p	q	p	q	
pERT87-1	1.3	BstNI	3.1	2.5/0.6	0.63	0.37	
-		XmnI	8.7	7.5	0.66	0.34	
pERT87-8	1.3	BstXI	4.4	2.2	0.6	0.4	
-		Taq I	2.7/1.1	3.8	0.71	0.29	
pERT87-15	1.5	BamHI	7.1/2.3	9.4	0.62	0.38	
-		TaqI	3.1	3.3	0.67	0.33	
		XmnI	1.6/1.2	2.8	0.68	0.32	

The three DXS164 subclones are listed together with the sizes of their cloned human DNA inserts. The enzyme site variation detected by each probe is represented by the sizes of the hybridizing fragments and the respective frequencies of the common allele (p) and the rare allele (q). The allele frequencies were calculated in each case from the results obtained with over 75 X chromosomes.

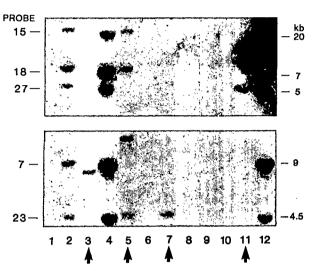

Fig. 2 Demonstration of four deletion breakpoints within the DXS164 locus. The DXS164 locus was expanded by chromosome 'walking' described prevously1. A schematic drawing of 137 kb of contiguous human DNA is presented at the top. Solid bars represent regions of repeated DNA sequences; open boxes represent regions of unique sequence. Cross-hatched boxes represent moderately repeated sequences, and two copies of LINE are indicated by the letter L. The numbers beneath the schematic diagram give the designations for five of the unique-sequence subclones used to determine the extent of deletions in DNA samples from nine DMD males. After digestion with PstI, each DNA sample was tested for the presence or absence of various human PstI fragments by hybridization²² with the various subclones. In the two different autoradiographs presented, the hybridizing PstI fragment for each subclone is indicated to the left of the figure; these are evident in lanes 2, 4 and 12, where the DNA samples isolated from individuals who do not bear deletions of DXS164 subclones are presented. The sizes of the respective PstI hybridizing fragments for normal individuals are given to the right of the figure. The DXS164 subclones pERT87-18, -15 and -27 were radiolabelled separately¹¹ and hybridized simultaneously to a nitrocellulose filter containing the 12 immobilized PstIcleaved DNA samples. The DXS164 subclones pERT87-7 and -23 were also radiolabelled separately and hybridized together to a duplicate nitrocellulose membrane with the same immobilized PstI-cleaved DNA samples. The different hybridization intensities of the PstI fragments were due to differences in specific activity and hybridization characteristics of the individual probes. Lines 4 and 12 contained 5 µg of PstI-cleaved DNA, whereas the others each contained $\sim 1~\mu g$. Lanes 1, 6 and 8-10 show no hybridization for any of the five DXS164 subclones. Lanes 3, 5, 7 and 11 (arrowed) exhibit at least one DXS164-hybridizing PstI fragment. The deletion DNA sample in lane 3 exhibits an absence of the subclones (left-hand side), pERT87-27, -15 and -18 and has a single altered PstI fragment for one of the subclones on the right-hand side (either pERT87-7 or -23). The altered fragment is presumably detected by the 23 subclone, and the hybridization results indicate that the deletion breakpoint occurs near pERT87-23 and the deletion extends in a leftward direction. The DNA sample in lane 7 exhibits similar hybridization results to the sample in lane 3, but the pERT87-23 hybridizing PstI fragment is normal in size. This DNA sample is presumed to have a different deletion breakpoint between pERT87-7 and pERT87-23 compared with that in lane 3 and the deletion also extends to the left. The DNA sample in lane 5 exhibits a normal-sized PstI hybridizing fragment for pERT87-23, a rare allele of a PstI RFLP detected by pERT87-7 (~10% of both normal and DMD males exhibit this larger PstI fragment) and normal-sized hybridizing PstI fragments for pERT87-18 and -15. The pERT87-27 subclone exhibited no hybridization. This DMD male has not been previously shown to have a deletion of pERT87-8 or -1 and has a deletion which starts between pERT87-15 and pERT87-27 and extends also to the left. The DNA sample in lane 11 carries a deletion which breaks near that presented in lane 5, but the deletion extends in the opposite direction. pERT87-27 hybridizes to a normal-sized PstI fragment whereas the remaining subclones are absent.

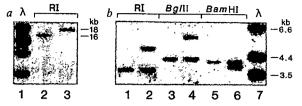

Fig. 3 Demonstration of deletion breakpoints for two independent deletions. Restriction enzyme cleavage, radiolabelling and hybridization were as described in Fig. 2 legend and ref. 1. In a, a deletion sample previously shown to carry pERT87-1 and a normal-sized hybridizing PstI fragment, showed no hybridization for pERT87-8 or other subclones to the left of this one. Subclone pERT87-14, between pERT87-1 and -8, was used to detect by hybridization an altered EcoRI fragment in the deletion DNA sample (lane 2; compare with a normal-sized EcoRI fragment in lane 3). The normal EcoRI fragment stretches across pERT87-8 and, based on other restriction enzyme sites in the region, the breakpoint of this deletion has been determined to fall between the right side of pERT87-8 and a PstI site 1.5 kb farther to the right. b, Demonstration of a deletion breakpoint detected with the pERT87-1 subclone. The deletion sample originally shown to be a deletion for pERT87-15 and -8 exhibits a break just to the left of pERT87-1. Lanes 1, 3 and 5, EcoRI, Bg/III and BamHI digests, respectively, of a normal male; lanes 2, 4 and 6, EcoRI, BglII and BamHI digests, respectively, of DNA isolated from a female heterozygous for the deletion. Both EcoRI and Bg/II reveal a larger altered fragment than BamHI. The deletion breakpoint lies ~500-1,000 bp to the left of pERT87-1.

Figure 3 shows two such determinations for two independent deletions. In one case (Fig. 3a, lane 2), an altered hybridizing EcoRI fragment is detected with the pERT87-14 subclone (located between pERT87-8 and pERT87-1). Comparison of the size of the altered EcoRI fragment with that seen in normal individuals (Fig. 3a, lane 3) and the knowledge that pERT87-8 is absent indicate that this deletion breakpoint maps between the pERT87-8 segment and an unaltered PstI site 1.5 kb towards pERT87-14. In the other example, different-sized hybridizing fragments for EcoRI (5.0 kb), BglII (5.8 kb) and BamHI (3.9 kb) were observed in the DNA sample isolated from a female heterozygous for a deleted X chromosome. A sample isolated from an unaffected male (Fig. 3b, lanes 1, 3, 5) exhibited the normal hybridizing fragments for the three enzymes.

Most deletions were found to be larger than 137 kb, for no subclone from within the entire cloned region was found to be. present. Among the 57 deletions tested, 24 showed the presence of some subclones but not others (the data are summarized in Fig. 4); these were deletions which had breakpoints within previously cloned DNA of the DXS164 locus. Fourteen deletions break on the left side of the cloned DNA and extend in the rightward direction off the DXS164 map towards the centromere (the direction of the DXS164 map relative to the centromere was established by analysing some deletion samples with the XJ-1.1 cloned segment; see Fig. 4 legend). Nine deletions break on the right of the map and extend in a leftward direction away from the centromere. Although some deletions are presented as similar, most have been shown to have independent breakpoints within the DXS164 locus (see Fig. 4 legend) and are schematically presented together when the breakpoints are near each other. It is apparent from Fig. 4 that there is a common region which is absent from almost all deletions except the six shown in the lower part of the figure. This region of common deletion overlap may be slightly biased due to the fact that the first probe made available to other investigators was pERT87-8, which resides near the overlap region. Further studies on additional DMD boys using all the DXS164 subclones should confirm whether this common region of overlap contains DNA sequences important for the expression of the DMD phenotype, or whether it represents an ascertainment bias.

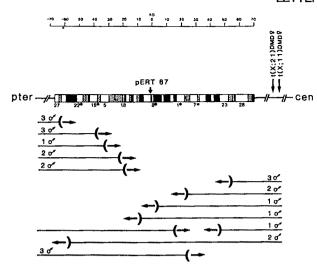

Fig. 4 A schematic representation of deletion breakpoints in the DXS164 locus. Fifty-seven DNA samples (53 samples shown to be deletions of one of the distributed subclones and 4 additional DNA samples shown to be deletions of either XJ-1.1 (ref. 2) or other DXS164 subclones) were tested for the absence or presence of various DXS164 subclones as presented in Figs 2, 3. Twenty-four of the 57 DNA samples showed the presence of at least one DXS164-hybridizing PstI fragment, whereas the remaining 33 DNA samples exhibited no DXS164-hybridizing PstI fragmentthe entire 137 kb was missing. By using a combination of subclones including those exemplified in Fig. 2, the approximate positions of the 24 different breaks were determined and are indicated by a bracket with an arrow indicating the direction of the missing DNA. Certain breakpoints which were similar are combined, and the number of males combined is indicated at the side of the figure. Nine deletion breakpoints were determined to the extent where an aberrant hybridizing restriction fragment was identified; these are localized within a few kilobases within the DXS164 locus. Nine deletions were determined to be different from the first nine, as revealed by the pattern of their hybridization with DXS164 subclones, but an altered restriction fragment has yet to be identified and these are thus only localized to within 1-5 kb. Six deletion breakpoints (the most recently acquired) were only mapped to 10-30-kb regions of the DXS164 locus and have not been definitely shown to differ from the other 18. Some of the deletions presented have also been tested for hybridization with the previously described clone XJ-1.1 (ref. 2): of those tested that break within DXS164 and extend to the right, all show no hybridization with XJ-1.1. For those tested that break in DXS164 and extend to the left, XJ-1.1 is present. The hybridization results with XJ-1.1 allow localization of the DXS164 subclones relative to the centromere as well as the (X; 21) translocation breakpoint, as indicated in the figure. Four of the six deletion DNA samples depicted at the bottom of the figure were not determined to be deletions by the original subclones pERT87-1, -8 or -15; two were found to be deletions for the XJ-1.1 cloned segment and were subsequently mapped with additional DXS164 clones, and the remaining two deletions were detected only with the leftmost DXS164 subclone, pERT87-27.

Screening of boys with additional pERT87 subclones and with the XJ-1.1 clone detected four deletions which would not have been detected with the originally distributed clones. These deletions were found among 269 boys who had been shown previously not to carry deletions of the pERT87-1, -8 or -15 subclones. These four deletions are not included in the data presented in Table 1 but are shown in Fig. 4; it is assumed that the true proportion of DMD and BMD boys who have deletions of portions of their X chromosomes would be greater than that presented in Table 1, where only three probes were used. Analysis of DMD or BMD DNA samples with the most distal pERT87-27 subclone, the three central subclones pERT87-1, -8 and -15, and the XJ-1.1 subclone should detect most of the deletions that are currently detectable.

The breakpoints of six deletions are different from most others; these are shown at the bottom of Fig. 4. One deletion is completely encompassed within cloned DNA and removes only 45 kb of DNA. Three deletions break within this 45-kb region and extend off the map towards the centromere; two of these were originally detected by the more centromeric cloned segment XJ-1.1 and subsequently mapped within the DXS164 locus. Two other deletions (detected with subclones of DXS164 other than pERT87-1, -8 and -15) break at the extreme left end of the cloned DNA and extend off the map for an undetermined distance. The central location of DXS164 subclones 1, 8 and 15 to DMD and/or BMD mutational sites, inferred from family studies and translocation breakpoint mapping, is substantiated by these additional deletion DNA samples. The profile of deletion breaks indicates that there must be a large segment of DNA which, when disrupted, can yield the phenotype of DMD and/or BMD. The fact that large deletions yield a DMD phenotype similar to that of other DMD boys who have not been demonstrated to bear deletions, indicates that the product of the locus can be either completely absent or aberrant and still yield a similar clinical picture.

The pattern of deletions implies that the gene(s) responsible for DMD must lie on a very large segment of X-chromosomal DNA. This is substantiated by the fact that recombinants are observed between cloned segments in the region and some disease mutation sites. For the future of diagnosis, the deletions represent a ready means of obtaining additional cloned segments from the other side of those deletions that break within DNA that has already been cloned. These junctional fragments from deletion patients are presently being cloned and the development of new RFLP-detecting probes to mark the entire region in which mutation can yield DMD and BMD is imminent. The deletion breakpoints also demarcate the regions of the DXS164 locus that might contain information important for the expression of the gene responsible for DMD and/or BMD. Analysis of these breakpoints at the level of the nucleotide sequence may also elucidate the mechanism underlying the deletions.

We thank all the families and patients involved in this study. We also acknowledge the many funding agencies who provided support for this work, especially the Muscular Dystrophy Association of America, the Muscular Dystrophy Group of Great Britain and Northern Ireland, the Muscular Dystrophy Association of Canada, and members of the European Alliance of Muscular Dystrophy Associations. We also thank the clinical geneticists, paediatricians and neurologists who brought to our attention the many Duchenne and Becker muscular dystrophy patients.

Carcinogen-specific mutation and amplification of Ha-ras during mouse skin carcinogenesis

Miguel Quintanilla, Ken Brown, Martin Ramsden* & Allan Balmain

Beatson Institute for Cancer Research, Switchback Road, Bearsden, Glasgow G61 1BD, UK

Cellular proto-oncogenes can be activated by both point mutations and chromosomal translocations, suggesting that there may be a direct link between exposure to agents which damage DNA and genetic change leading to malignancy (see refs 1, 2 for reviews). Several groups have therefore analysed mutations found in cellular oncogenes of tumours induced by particular physical or chemical carcinogens³⁻⁹. Here, we have analysed the molecular changes at different stages of carcinogenesis in mouse skin tumours induced by initiating and promoting agents. Over 90% of tumours, including premalignant papillomas, initiated with dimethylbenzanthracene (DMBA) have a specific A -> T transversion at the second nucleotide of codon 61 of the Harvey-ras (Ha-ras) gene. The frequency of this mutation was dependent on the initiating agent used, but not on the promoter, suggesting that the mutation occurs at the time of initiation. The mutation was heterozygous in most papillomas tested, but was homozygous or amplified in some carcinomas. The development of further chromosomal changes at the c-Ha-ras gene locus is therefore a common feature of tumour progression.

One of the consequences of ras gene mutation is that the resultant altered proteins (p21) exhibit aberrant mobilities on SDS gels^{10,11}. Alterations at codon 12 give rise to more slowly migrating forms of p21, while mutations at the other frequently affected locus around codon 61 usually produce rapidly migrating forms. Figure 1B (lane 5) shows the normal Kirsten-ras (Ki-ras) p21 immunoprecipitated from NIH 3T3 cells by monoclonal antibody Y13-259 (ref. 12). Transformants induced by transfection with DNA from a papilloma (Fig. 1B, lane 1) or a carcinoma (lane 3) synthesize in addition a p21 product encoded by the transforming Ha-ras gene, as shown using the Harveyspecific monoclonal antibody YA6-172, which immunoprecipitates only the faster migrating species (Fig. 1A, lane 1). Although the parental NIH 3T3 cells produce only small amounts of Harvey p21, a band can be detected after immunoprecipitation with YA6-172, which migrates at the front edge of the Ki-ras p21 band (Fig. 1A, lane 3). Comparison of lanes 1 and 3 of Fig. 1A indicates that the transforming Ha-ras encoded by the tumour DNAs has a substantially higher mobility on SDS gels and probably results from a mutation in the region of the gene surrounding codon 61. In an analysis of representative foci induced by seven tumours, six were shown to synthesize rapidly migrating forms of Ha-ras p21; four of these are shown in Fig. 1C, together with a slowly migrating p21 (lane 5) in a transformant induced by DNA from a Sencar carcinoma. We conclude from this analysis that most skin tumours initiated with DMBA probably have mutations around codon 61 of the mouse Ha-ras gene, but a minority exhibit mutations at or around codon 12.

Restriction fragment length polymorphisms (RFLPs) have been used to demonstrate directly the presence of mutated *ras* genes in samples of DNA from human or animal tumours^{7,13,14}. To attempt this experimental approach, we first obtained a genomic clone of the normal mouse cellular Ha-*ras* gene and sequenced coding exons 1 and 2 which contained, respectively, the putative mutable sites at codons 12 and 61 (M.R., K.B., F.

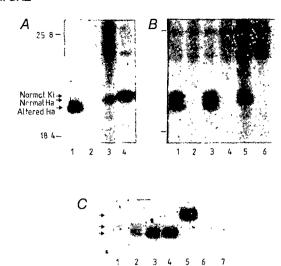

Fig. 1 Immunoprecipitation of ras p21 from NIH 3T3 transformants. A, Lanes 1, 2: NIH 3T3 transformant obtained by transfection with DNA from a primary carcinoma. Lanes 3, 4: NIH 3T3 cells. Lysates were immunoprecipitated with antibody YA6-172 (lanes 1, 3), normal rat serum (lane 2) or antibody Y13-259 (lane 4). B, NIH 3T3 transformants obtained by transfection with DNA from a papilloma (lanes 1, 2) or a carcinoma (lanes 3, 4). Lanes 5, 6: normal NIH 3T3 cells. Lysates in lanes 1, 3 and 5 were immunoprecipitated with Y13-259 and those in lanes 2, 4 and 6 with normal rat serum. C, NIH 3T3 transformants obtained by transfection with DNA from individual papillomas (lanes 1-3) or carcinomas (lanes 4, 5), all immunoprecipitated with YA6-172. Lanes 6 and 7: lysates from NIH 3T3 cells immunoprecipitated with YA6-172 or normal rat serum respectively.

Methods. Isolation of DNA by lysis of frozen tumours in 5 M guanidinium thiocyanate and centrifugation through CsCl has been described previously^{3,9}. NIH 3T3 transformants obtained by calcium phosphate-mediated transfection of DNA from primary tumours were grown to subconfluence in Special Liquid Medium (Flow) containing 10% fetal bovine serum. Cultures were labelled by incubation for 18 h in methionine-free medium containing 5% dialysed fetal bovine serum in the presence of 35S-methionine (NEN; specific activity 1,000 Ci mmol⁻¹, 200 μCi per ml of medium). Cells were lysed essentially as described by Furth et al.12 and aliquots $(3-5 \times 10^7)$ acid-precipitable c.p.m.) of the lysate incubated with monoclonal antibody YA6-172 or Y13-259, or normal rat serum. Antigen-antibody complexes were precipitated with protein A-Sepharose coated with rabbit anti-rat IgG (Sera Labs). Precipitates were washed six times in lysis buffer and run on 12.5% polyacrylamide gels as described by Laemmli²⁵. Gels were treated for fluorography with Enlightening (NEN), dried and exposed to Kodak film at -70 °C using intensifying screens.

Fee, R. Krumlauf and A.B., manuscript in preparation). The sequence around codon 61, which appeared to be the most frequently mutated locus in DMBA-initiated tumours, is shown in Fig. 2B. Clearly, an $A \rightarrow T$ transversion at this position could give rise to a new restriction site for the enzyme XbaI. Digestion with XbaI of DNA samples from the NIH 3T3 transformants shown in Fig. 1 revealed the presence of novel hybridizing fragments in all but one of the foci tested (Fig. 2A, lane a). This particular focus is that which exhibited the slowly migrating p21 (Fig. 1C), presumably because of a codon 12 mutation, and would therefore not be expected to show any change in the sequence of codon 61. Most foci had novel fragments of \sim 4 and 8 kilobases (kb) but some had aberrant bands due to the loss of one or more of the flanking XbaI sites during integration of the transfected DNA (Fig. 2A, lanes f-h).

The XbaI polymorphism enabled us to verify that the codon 61 mutation was present in the primary mouse skin tumours, and was not an artefact of the transfection procedure. Table 1 shows that 90% of DMBA-initiated tumours from three mouse strains had the same mutation. Figure 3A, lanes a and e, shows

^{*} Present address: Glaxo Research Laboratories, Ulverston, Cumbria LA129DR, UK

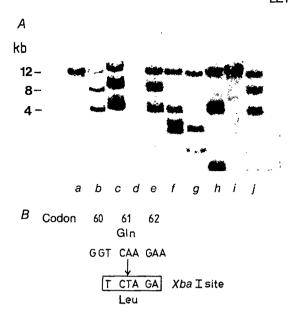

Fig. 2 XbaI polymorphism in NIH 3T3 transformants. A, DNAs derived from NIH 3T3 transformants obtained by transfection with papilloma (lanes d-h, j) or carcinoma (lanes a-c) DNAs were digested with XbaI and hybridized on Southern blots with an Ha-ras-specific probe. Lane a contains DNA from a transformant with the slowly migrating p21 protein shown in Fig. 1C. Lane i contains DNA from a spontaneous NIH 3T3 transformant and has the same hybridization pattern as normal DNA. B, Induction of an XbaI polymorphism by a specific mutation at codon 61. Digestion of normal mouse DNA with XbaI gives rise to a 12-kb fragment containing the mouse c-Ha-ras gene. Mutation of the middle base of c codon 61 from A to A would give rise to a new A site, generating tumour-specific fragments of A and A kb.

Methods. Aliquots (10 μg) of DNA from different transformants were digested with a 5-10-fold excess of XbaI (BioRad) under the conditions recommended by the suppliers. DNAs were run on 1% agarose gels, and transferred to nitrocellulose filters (Sartorius) according to Law et al. 26. Purified insert from the plasmid BS9 (ref. 27) was nick-translated and blots were hybridized at 42 °C in 50% formamide buffer as described previously 3. Blots were normally washed to a final stringency of 0.5×SSC at 65 °C, then exposed to Kodak X-OMAT film for 1-3 days at -70 °C with intensifying screens.

the typical pattern observed in 90% of the papillomas. Both the normal 12-kb band and those derived from the mutated allele are evident, and in almost all cases the band corresponding to the normal fragment is the most intense. Since histological analysis shows that papillomas consist predominantly of epithelial cells with a relatively small proportion of contaminating stroma cells, we conclude that the mutation is probably heterozygous in these premalignant tumours. A small proportion (\sim 10%) of the papillomas tested showed no evidence of the XbaI polymorphism (see, for example, Fig. 3A, lane d).

Figure 3A also shows the results of an analysis of a series of carcinomas initiated with DMBA. All the carcinomas from NIH mice exhibited the XbaI polymorphism, but in some cases, the relative intensity of the bands diagnostic of the mutated allele was considerably stronger than in the papillomas (Fig. 3A, lanes b, f-h, k). Figure 3B shows the pattern obtained after rehybridization of the same blot with a single-copy probe for the mouse interleukin-3 (IL-3) gene¹⁵. Comparison of the relative band intensities demonstrates that the mutated allele of the c-Ha-ras gene has become amplified in the carcinomas shown in lanes f-h. Those shown in lanes b and b, which contain more DNA and therefore do not provide clear evidence of amplification, nevertheless exhibit a change in the relative amounts of 'normal' 12-kb and 'mutated' 4- and 8-kb fragments. This result suggests that homozygosity may have developed in these cases, although

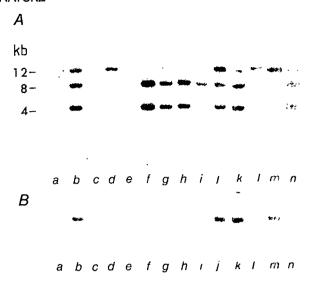

Fig. 3 Demonstration of the XbaI polymorphism in primary tumours. A, Lanes a, d and e: DNAs obtained from DMBA initiated primary papillomas. Lanes b, c and f-k contain NIH carcinoma DNAs. The pattern obtained with normal DNA is shown in lane l. Lanes m and n contain respectively DNA from spontaneously transformed NIH 3T3 cells and an NIH 3T3 transformant obtained by transfection with DNA from a papilloma with the codon 61 polymorphism. DNAs were digested with XbaI, run on agarose gels and hybridized with an Ha-ras-specific probe as described in Fig. 2 legend. B, Autoradiograph showing the ~ 1 -kb band obtained by rehybridization of the blot shown in A with a complementary DNA probe for the IL-3 gene¹⁵ (provided by A Dunn).

loss of the normal allele is difficult to prove because of the presence of some normal cells in the tumours. Yet another pattern is seen in the carcinomas in lanes c, i and j, which have similar band ratios to the papillomas.

The high frequency of the XbaI polymorphism in DMBAinitiated tumours allowed us to determine whether this mutation is carcinogen-specific, or is detected in tumours induced by different carcinogenic initiators or promoters. Chryserobin is a strong tumour promoter and a derivative of anthralin16. Compounds of this type are structurally unrelated to tetradecanoyl phorbol 13-acetate (TPA), do not bind to the phorbol ester receptor¹⁷ and presumably have a different site of action within the target cell. The results shown in Table 1 suggest that the nature of the promoter used does not influence the frequency of the specific XbaI polymorphism seen in DMBA-initiated tumours. However, of a total of 12 tumours from NIH mice initiated with N-methyl-N'-nitro-N-nitrosoguanidine (MNNG), comprising six papillomas and six carcinomas, none showed the restriction fragments diagnostic of the mutation. The carcinogen MNNG is a direct-acting methylating agent and might therefore not be expected to induce the same types of mutation as DMBA¹⁸. Since the mice were initiated by a single treatment with the carcinogen, the presence of the polymorphism in tumours initiated with one type of initiator, but not with another, suggests that the Ha-ras gene mutations occur at or very close to the time of initiation.

Zarbl et al.⁷ recently showed that specific $G \rightarrow A$ transitions occur consistently at the second nucleotide of codon 12 of the rat c-Ha-ras gene in rat mammary carcinomas induced by a single treatment with nitrosomethylurea (NMU). As this particular mutation is exactly that predicted on the basis of the known mechanism of action of NMU¹⁸, Zarbl et al. concluded that NMU interacts directly with codon 12 of the ras gene. Our observation that Ha-ras mutations in DMBA-initiated tumours occur predominantly at adenosine residues is compatible with previous results on the metabolism and binding of DMBA to

Table 1	in tumours			
Strain	Tumour	Initiator	Promoter	No. positive
				no. tested
Sencar	Papilloma	DMBA	TPA	12/14
	· .	DMBA	Chryserobin	5/5
NMRI	Papilloma	DMBA	TPA	2/2
NIH	Papilloma	DMBA	TPA	3/3
Sencar	Carcinoma	DMBA	TPA	0/2*
NMRI	Carcinoma	DMBA	TPA	3/3
	(transplanted)		•	
NIH	Carcinoma	DMBA	TPA	8/8
NIH	Papilloma	MNNG	TPA	0/6
NIH	Carcinoma	MNNG	TPA	0/6

Mice were initiated with 25 µg DMBA or 600 µg MNNG, dissolved in 200 µl acetone., Promotion was carried out twice weekly by treatment with an acetone solution of TPA (12.5 μg) or chryserobin (50 μg)¹⁶

One tumour has an Ha-ras mutation, presumably at codon 12 (see Fig. 1C, lane 5).

DNA in mouse skin. Dipple and co-workers have shown that benzo(a)pyrene, which is about 30-fold weaker as an initiating agent than DMBA, exhibits a corresponding decrease in the amount of binding to deoxyadenosine, but not deoxyguanosine, residues^{19,20}. The relative carcinogenic potency of these two aromatic hydrocarbons may be related to their abilities to bind to, and therefore induce mutations at; deoxyadenosine. The mutations in DMBA-induced tumours are not exclusively A > T transversions, however, as a small proportion of tumours are activated at codon 12, presumably by changes at one of two G residues.

If Ha-ras gene mutation is critically involved in initiation of mouse skin carcinogenesis, the introduction of a mutated gene into epidermal cells in vivo should be able to substitute for treatment with the initiating chemical. We have shown recently that the viral Ha-ras gene of Harvey sarcoma virus can act as an initiator of two-stage skin carcinogenesis21. These results support the conclusion that Ha-ras gene mutation occurs during initiation, but this event in itself is insufficient for tumorigenesis because even epidermal cells initiated with the viral Ha-ras gene required promoter treatment before papillomas developed

These studies suggest that mutation and amplification of ras genes may occur at different stages of carcinogenesis. It is possible that the additional changes involving the mutated allele may take place at the time of carcinoma development, or may be present in a sub-set of papillomas with a high probability of malignant conversion²². Indeed, one of 22 papillomas in the present studies showed amplification of the mutated allele (data not shown). We do not know whether these changes are accompanied by loss of the normal allele of the Ha-ras gene; loss of the normal allele has been seen in a carcinogen-induced thymic lymphoma²³ and in human tumour cell lines¹³, and loss of one Ha-ras allele has been reported in a series of bladder carcinomas²⁴. Chromosomal changes of this kind may represent late events in tumour development in some, but by no means all, mouse skin carcinomas.

M.Q. is the recipient of an EMBO long-term Fellowship and K.B. is supported by a Training Fellowship from the MRC. We thank I. B. Kerr for histological diagnosis of tumours, Francis Fee and Sheena Young for technical assistance, and J. Paul for critical reading of the manuscript. Some of the tumours used in this study were supplied by G. T. Bowden, T. Slaga and J. Di Giovanni. The Beatson Institute is funded by the Cancer Research Campaign.

Site-directed mutagenesis of the regulatory light-chain Ca²⁺/Mg²⁺ binding site and its role in hybrid myosins

Fernando C. Reinach*, Kivoshi Nagai† & John Kendrick-Jones†

* Ludwig Institute for Cancer Research and † MRC Laboratory of Molecular Biology, MRC Centre, Hills Road, Cambridge CB2 2QH, UK

The regulatory light chains, small polypeptides located on the myosin head, regulate the interaction of myosin with actin in response to either Ca2+ or phosphorylation. The demonstration that the regulatory light chains on scallop myosin can be replaced by light chains from other myosins has allowed us to compare the functional capabilities of different light chains1, but has not enabled us to probe the role of features, such as the Ca2+/Mg2+ binding site, that are common to all of them. Here, we describe the use of site-directed mutagenesis to study the function of that site. We synthesized the chicken skeletal myosin light chain in Escherichia coli and constructed mutants with substitutions within the Ca²⁺/Mg²⁺ binding site. When the aspartate residues at the first and sixth Ca2+ coordination positions are replaced by uncharged alanines, the light chains have a reduced Ca2+ binding capacity but still bind to scallop myosin with high affinity. Unlike the wild-type skeletal light chain which inhibits myosin interaction with actin, the mutants activate it. Thus, an intact Ca²⁺/Mg²⁺ binding site in the N-terminal region of the light chain is essential for regulating the interaction of myosin with actin.

The myosin regulatory light chains belong to a family of calcium-binding proteins which includes calmodulin and troponin C²⁻⁴. These are composed of four EF hands or domains, each consisting of an α -helix E, a divalent cation binding loop and an α -helix F (refs 5-7). In the myosin regulatory light chains, deletions and non-conservative substitutions at critical positions have destroyed the Ca²⁺/Mg²⁺ binding ability of three of the loops, so that only the N-terminal domain has retained the ability to bind divalent ions⁸⁻¹¹.

The regulatory light chains are non-covalently bound to the heavy chains in the neck region of myosin heads 12-15. They can be subdivided into three functional classes: (1) in molluscan muscles, they inhibit myosin interaction with actin in the absence of Ca²⁺ and Ca²⁺ relieves this inhibition¹; (2) in vertebrate smooth muscle and non-muscle cells, Ca²⁺ binding to calmodulin activates a kinase which phosphorylates the regulatory light chains and thus 'switches on' myosin interaction with actin^{16,17}; (3) in vertebrate striated muscles, they do not appear to have a primary role in actomyosin regulation^{18,19}.

When the regulatory light chains are removed from scallop myosin by EDTA, myosin interaction with actin as measured by the actin-activated myosin MgATPase is 'desensitized' to Ca²⁺ and Ca²⁺ sensitivity can be restored when the scallop light chains rebind^{20,21} (Table 1). Regulatory light chains from a wide

Table 1 Effect of the light-chain mutants on Ca²⁺ regulation in desensitized scallop myofibril-regulatory light chain hybrids

Desensitized scallop myofibrils	Actomyosin -Ca ²⁺ (µmol H ⁺ m	+Ca ²⁺
Control	0.163	0.152
+scallop LC	0.050	0.263
+rabbit LC	0.050	0.081
+chicken LC	0.058	0.102
+ E. coli LC	0.050	0.069
+ mutant 442 LC	0.262	0.233
+mutant 452 LC	0.229	0.200
+ mutant 463 LC	0.251	0.231

The desensitized scallop myofibril-regulatory light chain hybrids were prepared as described in Fig. 2B legend. Their actin-activated Mg AT-Pase activities were measured at 25 °C in a final concentration of 36 mM KCl, 3 mM MgCl₂, 2 mM MgATP and either 0.1 mM EGTA (-Ca²⁺) or 0.1 mM EGTA and 0.15 mM Ca²⁺ (+Ca²⁺) by the pH-stat assay procedure as described previously¹. Samples (1 mg) of each of the hybrids were solubilized in 0.6 M KCl, 1 mM MgATP, pre-mixed with 0.5 mg skeletal muscle F-actin (actin filaments) in a final volume of 200 µl, and then diluted to 5 ml to give the final assay conditions shown above. The mutant light chains remain bound to the desensitized scallop myosin under these assay conditions. These ATPase assays were repeated with three other desensitized scallop myofibril preparations and with the light chain/mutant hybrids prepared under the various conditions described in Fig. 2B legend. We observed that under all the conditions tested the native and wild-type vertebrate light chains always inhibited the actin-activated myosin ATPase whereas the mutant light chains always activated the ATPase. LC, light chain.

variety of myosins will also bind to desensitized scallop myosin to form hybrid myosins and their function can be assayed¹. The three classes of light chains regulate the actin-activated ATPase of hybrid scallop myofibrils as follows: those from molluscan muscles regulate in a calcium-dependent fashion, whereas those from vertebrate smooth muscle and non-muscle cells regulate in a phosphorylation-dependent manner¹⁷ and those from vertebrate striated muscles inhibit the ATPase activity²². There is no evidence that the divalent cation binding site in any of these three classes of regulatory light chains is involved in Ca²⁺ regulation^{11,23}, and thus the precise role of this site is not known. We have prepared chicken skeletal regulatory light-chain mutants with genetically engineered substitutions in the Ca²⁺/Mg²⁺ binding loop, determined the Ca²⁺ binding capacity of these mutants and assayed their regulatory function using desensitized scallop myofibrils.

A plasmid plcIIFXMLC was constructed which directed the synthesis of a fusion protein consisting of the N-terminal 31 amino-acid residues of λ cII protein, the blood coagulation factor X_a recognition site and the complete chicken myosin light-chain (MLC) polypeptide (Fig. 1). Because the amino-acid sequence near the factor X_a cleavage site, Arg-Ala-Pro-Lys, resembles the thrombin cleavage site in fibrinogen²⁴, we digested the fusion protein CIIFXMLC with bovine thrombin. This enzyme cleaved the fusion protein at a single site to yield a

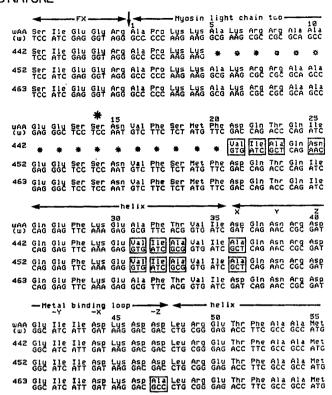

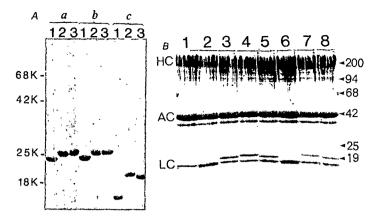

Fig. 1 Sequence of the factor X recognition site (FX) and the first 55 amino acids of the myosin regulatory light-chain clone present in pLcIIFXMLC Arrow, thrombin cleavage site. The nucleotide and amino-acid sequences of the wild-type light chain (wAA), mutants 442, 452 and 463 are indicated. Where the nucleotide and amino-acid sequences of the three mutant light chains are different from the wild type the residues are boxed. The deletion present in clone 442 is marked with asterisks. The residues involved in the α -helix-Ca/Mg binding loop- α -helix, which are believed to form a EF-hand structure, are indicated. The six residues believed to be involved in the Ca/Mg coordination are also indicated (X, Y, Z, -Y, -X, -Z). The phosphorylation site is indicated with a large asterisk.

Methods. Construction of the expression plasmid. The EcoRI insert of clone Agt11/L10 containing the whole coding region of chicken myosin light chain 2 (see Fig. 5 of ref. 25 for sequence) was treated with the Klenow fragment of DNA polymerase in the presence of dNTP to obtain flush ends and cloned into the SmaI site of M13mp19. A clone (M13MLC) containing the insert with the 5' end of the messenger RNA facing the universal priming site, was selected. A Sau96I fragment of M13MLC from position 33 to 253 was isolated, treated with Klenow DNA polymerase in the presence of dNTP to obtain flush ends, and cloned in the StuI site of M13mp11 (ref. 27). A clone (M13mp11FXMLC1) where the Ala codon of the insert was in-frame with the FX recognition sequence and facing the universal priming site of M13, was selected. The Ncol (position 194)-HindIII (polylinker) fragment from M13MLC was then cloned into the NcoI-HindIII-cleaved M13mp11FXMLC1 to obtain M13mp11FXMLC2. This clone contains the whole MLC coding and 3' noncoding region linked in-frame to the FX recognition site. The BamHI fragment from M13mp11 FXMLC2 containing FX sequences and MLC sequences up to position 364 was cloned into the BamHI site of pLcII (ref. 28) and a clone (pLcIIFXMLC1) with the FX recognition sequence in-frame with the first 31 amino acids of cII was selected by restriction enzyme analysis. Finally, the NcoI (194)-HindIII (polylinker) fragment of M13MLC was cloned into NcoI-HindIII-cleaved pLcIIFXMLC1 to obtain pLcIIFXMLC2. This clone contains the pL promoter of λ followed by nutL, nutR, tR₁ and the first 31 amino acids of cII. The sequence at the junction of FX and MLC is shown. The EcoRI-HindIII fragment of pLcIIFXMLC2 was subcloned into M13mp19 to obtain M13mp404. Single-stranded templates of M13mp404 were used to sequence the final construct with the help of synthetic oligonucleotides spaced along the insert. Construction of mutants. Single-stranded DNA from clone M13mp404 and oligonucleotides synthesized using the phosphotnester method (5'GGTGATCGCTCAGAACC to change Asp 36 to Ala and 5'TAAGGACGCCCTGCGGG also to change Asp 47 to Ala) were hybridized and extended with Klenow DNA polymerase and transfected into BMH-71-18-mutL (ref. 29). Mutant clones were identified by hybridization with the mutagenic oligonucleotide²⁷, plaque-purified and the whole *EcoRI-HindIII* insert was sequenced before recloning into pLmp10 (ref. 28). Restriction enzymes were from New England Biolabs, Klenow DNA polymerase from Boehringer Mannheim and T4 DNA ligase was purified from strain NM989 (ref. 30). M13 constructs were grown in TG-1 (ref. 29) and pLcII constructs in QY13 (ref. 31).

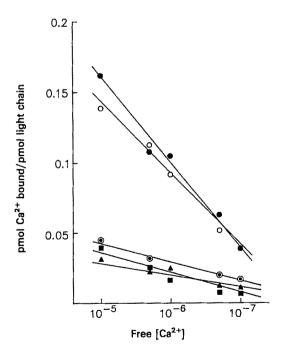

Fig. 2 A, Purification of light-chain mutants; B, SDS-PAGE (10-20% acrylamide gradient gel) of desensitized scallop myofibril/regulatory light chain hybrids. A, SDS (15%)-PAGE of: (1) mutant 442; (2) mutant 452; and (3) mutant 463 at the different stages in the purification procedure: a, cell/pellet fractions after 4 washes with Triton X-100 solution; b, mutant light-chain fusion proteins cIIFX-MLC after purification on DEAE-cellulose; c, mutant light chains after removal of the bacterial leader sequence by thrombin cleavage and DEAE-cellulose chromatography. The gels were calibrated using the following M_r standards: 68,000 (68K), bovine serum albumin; 42K, actin; 25K, rabbit skeletal muscle myosin A_1 (LC₁) light chain; 18K, rabbit myosin regulatory (LC₂) light chain. B, The hybrids were as follows: 1, control, desensitized scallop myofibrils alone; 2, +scallop light chains; 3, +rabbit skeletal muscle myosin light chains; 4, +chicken breast muscle myosin light chains; 5, +E. coli-synthesized light chains (wild type); 6, +light-chain mutant 442; 7, +mutant 452; and 8, +mutant 463. The following M_r standards were used: 200K, myosin heavy chain; 94K, phosphorylase; 68K, bovine serum albumin; 42K, actin; 25K, rabbit myosin A_1 (LC₁) light chain; 19K, chicken myosin LC₂ light chain. HC, myosin heavy chain; AC, actin; LC, light chains. The myofibril samples have been overloaded so that the light chains, which are present only as ~4% of the total

protein, can be clearly distinguished. In scallop myosin the two types of light chains (structural and regulatory) have the same mobility, and desensitization leads to the removal of only the regulatory light chains from the myosin²¹

to the removal of only the regulatory light chains from the myosin²¹.

Methods. A, QY13 cells containing pLcIIFXMLC or the mutated constructs were grown at 30 °C in 2×TY medium (containing 25 µg ampicillin per ml). At $A_{600\,\mathrm{nm}} = 0.8$ the cultures were quickly warmed to 42 °C and maintained at this temperature for 15 min, then grown at 37 °C for 3.5 h. The cell pellets were prepared as described 31, washed four times with 0.5% Triton X-100, 1 mM EDTA (shown in a) 32, dissolved in 6 M urea, 50 mM Tris-HCl, pH 7.5, 0.5 mM MgCl₂, 0.5 mM dithiothreitol (DTT), dialysed against the same solution for 3 h and then applied to a 11×4 cm DEAE-cellulose column (Whatman DE-52) equilibrated in the same solution. The fusion proteins were eluted with a linear gradient (500+500 ml) from 0 to 80 mM NaCl in the 6 M urea solution, and the peak fractions concentrated in an Amicon ultrafiltration cell with a PM-10 membrane (b). The proteins (5 mg ml⁻¹) were dialysed against two changes of 100 mM NaCl, 40 mM Tris-HCl, pH 8.0, 0.5 mM DTT and then digested at 20 °C for 2.5 h with thrombin (enzyme/protein (w/w) ratio 1:250). The digests were diluted with an equal volume of 4 M urea, 25 mM Tris-HCl, pH 7.5, 0.5 mM MgCl₂, 0.5 mM DTT (to reduce the NaCl concentration to 50 mM), loaded onto a 8×4 cm DEAE-cellulose column equilibrated in 2 M urea, 25 mM Tris-HCl, pH 7.5, 0.5 mM MgCl₂, 0.5 mM DTT and the light chains eluted with a linear gradient (400+400 ml) from 50 to 150 mM NaCl in the 2 M urea solution. The light chains were concentrated by ultrafiltration with an Amicon PM-10 membrane (c) and their protein concentrations measured assuming an E¹⁰⁰₁₀₀₀ = 5.5 (recovery > 80% of the initial fusion protein). Final yield was 20 mg purified light chain per 1 of bacterial culture. B, Scallop myofibrils were prepared and desensitized at 27 °C as described previously²¹. The hybrids were prepared by incubating desensitized scallop myofibrils (~2 mg ml⁻¹) in 50 mM NaCl, 4 mM MgCl₂, 5 mM phosphate buffer, pH 7.0, 0.2 mM DTT with the light chains and mutants at a 1.5:1 light chain/myosin heavy chai

polypeptide which co-migrated with the chicken skeletal myosin light chain on SDS gels. N-terminal sequence analysis of the cleaved protein gave the sequence Ala-Pro-Lys-Lys-Ala-Lys-Arg, which is identical to the N terminus of the light chain 10,25 except for the absence of the trimethyl blocking group on the N-terminal alanine residue²⁶. This light chain synthesized in E. coli bound to desensitized scallop myofibrils and inhibited the

Methods. Ca²⁺ binding was measured using a procedure adapted from that of Kawasaki et al.27 using a 96-well Microtiter hybrid dot manifold assembly (BRL, No. 1050 MM) and a nitrocellulose membrane filter (Schleicher & Schuel PH79, 0.1 μ m). Aliquots (2-5 μ l) containing 4-10 μ g of light chains/mutants were applied to the walls of the wells of the manifold and mixed with 250 µl of solution with the appropriate free Ca²⁺ concentration (10⁻⁵-10⁻⁷ M Ca²⁺ in 50 mM NaCl, 0.1 mM MgCl₂, 10 mM imidazole buffer, pH 7.0). These solutions were prepared using an apparent binding constant for Ca/EGTA at 25 °C and pH 7.0 of $3 \times 10^6 \,\mathrm{M}^{-1}$ (ref. 33) and with a final concentration of 5-20 μM ⁴⁵Ca/EGTA (specific activity 200-900 c.p.m. pmol⁻¹). The samples were mixed, incubated at 20 °C for 5 min and rapidly filtered on a vacuum pump. A fresh 250-µl aliquot of the appropriate Ca2+ solution was added and incubated at 20 °C for a further 5 min, and then filtered under vacuum. The nitrocellulose filter membrane was dried, wrapped in Saran wrap and autoradiographed at $-70\,^{\circ}\text{C}$ for 2 h. The regions of the nitrocellulose membrane containing the light chains/mutants could be identified from the autoradiograph and by the indentation caused by pressure and were excised with a one-hole punch, 'dissolved' in Aquasol-2 (NEN Research Products) and counted. Control wells with no added protein, but washed with the appropriate Ca/E01A-containing solutions, were used to correct for background. This procedure was checked by measuring the Ca²⁺ binding of the wild type and mutant light chains by the Hummel-Dryer technique³⁰ at 10^{-5} M free Ca²⁺ Ca²⁺ binding measurements were also carried out in the absence of Mg²⁺ and the binding curves obtained were very similar (~5-10% increase in Ca²⁺ binding) to those shown here in the presence of $100 \, \mu M \, Mg^{2+} \, Mg^{2+}$ was wells with no added protein, but washed with the appropriate 45Ca/EGTAincluded to eliminate background low-affinity nonspecific divalent cation

Fig. 3 Ca²⁺-binding ability of the regulatory light chain and mutants. O,

ATPase activity in an identical manner to the native regulatory light chain of chicken skeletal muscle.

binding. Binding measurements were repeated at least three times under each set of conditions.

In the divalent cation binding domains of the calcium-binding proteins, the acidic residues at the coordination positions X and -Z are conserved and are believed to bind to Ca^{2+} (refs 3, 4; Fig. 1). To inhibit Ca^{2+} binding in the light chain, we have separately replaced Asp 36 and Asp 47 with Ala at the X and

-Z coordination positions by oligonucleotide-directed mutagenesis. We sequenced a representative clone (463) of the Asp 47 → Ala mutant and showed that it contains no other substitutions. All the 36 clones sequenced in the experiment to produce the Asp 36 -> Ala mutant had three additional amino-acid substitutions in the E helix preceding the binding loop (Fig. 1). During the screening for Asp 36 -> Ala mutants, we found a clone (442) which contained in addition a deletion of 16 amino acids spanning the phosphorvlation site and four further amino-acid substitutions in the N-terminal region (Fig. 1). These mutants were produced in E. coli, purified and cleaved with thrombin. As expected, the protein produced from clone 442 was smaller (relative molecular mass $(M_r) \approx 17,000$) than the other mutants $(M_r \approx 19,000)$ (Fig. 2A).

We measured the relative Ca2+ binding abilities of the wildtype and mutant light chains at 10^{-7} to 10^{-5} M free Ca²⁺ and found that the Ca2+ binding capacities of the mutants were lower than that of the wild-type and native light chains (Fig. 3). All the mutants bound to desensitized scallop myfibrils with an affinity comparable with that of the wild type made in E. coli and native chicken myosin regulatory light chains (Fig. 2B). Table 1 shows that when scallop myofibrils were reconstituted with chicken skeletal myosin light chains or those of the wild type made in E. coli, the ATPase activity was inhibited both in the presence and absence of Ca²⁺, whereas the mutant light chains activated the ATPase to a level comparable with that observed with the scallop light chains in the presence of Ca²⁺. This shows that the mutant light chains have lost the ability to inhibit the interactions of myosin with actin and instead lock the actin-activated myosin ATPase in the 'on' state. Thus, they appear to bind to the myosin heavy chains in the correct positions needed to prevent the decrease in ATPase activity observed with the unregulated myosin heads (see Table 1 for control).

Furthermore, our results show that the first domain in the regulatory light chain really is the site with high affinity for divalent cations. The existence of light chains that differ in their physiological activities, a suitable myosin assay system and the generation of functional mutants in E. coli should allow us further to dissect the structural features responsible for myosin regulation.

We thank Drs Max Perutz, Hugh Huxley, Alexander MacLeod, Clive Bagshaw, Jane Mitchell, Sandra Citi, Lesley Clayton and Richard Turner for critically reading the manuscript; Ross Jakes for performing the N-terminal sequence analysis; Dr Peter Esnouf for the gift of factor X and thrombin; and Dr Hans C. Thøgersen for purified thrombin and for pointing out the similarity of the thrombin cleavage site in CIIFXMLC and fibrinogen. K.N. was supported by NIH grant RO1 HL 31461-02, F.C.R. was partially supported by CNPg grant 20.0694, Brazil.

Enzymatic activity of the conserved core of a group I self-splicing intron

Jack W. Szostak

Department of Molecular Biology, Massachusetts General Hospital, Boston, Massachusetts 02114, USA

Splicing of the Tetrahymena ribosomal intron was first studied by Cech et al.1,2, who subsequently demonstrated that the intron RNA catalyses its own excision from a primary transcript to yield mature ribosomal RNA^{3-5} . This intron shares several short conserved sequences and a common secondary structure with several other introns 6-9, some of which have also been shown to self-splice 10,11. Here I show that the conserved core of the Tetrahymena intron can act in trans to catalyse the sequence-specific cleavage and addition of guanosine to a separate RNA substrate.

Cech et al. proposed that self-splicing occurs by a series of trans-esterification reactions in which the total number of phosphodiester bonds is conserved^{4,12,13}. Each step involved the concerted breakage and formation of a specific phosphodiester bond, catalysed by a single phosphoester transferase activity contained within the intron RNA itself. In the first step, the 3' hydroxyl of a guanosine 12,14 attacks the phosphodiester bond between the 5' exon and the intron. That bond is broken and a new one is formed between the guanosine and the 5' end of the intron, thus conserving the total number of phosphodiester bonds. The second step is another exchange reaction; in this case the phosphodiester bond between the 3' end of the intron and the 3' exon is broken and a new one is formed between the 5' and 3' exons. In the third step, the intron circularizes itself in yet another trans-esterification reaction.

Examination of potential secondary structures shows that all three of these reactions may take place in a very similar structural context (Fig. 1). In each case, the reaction is between one strand of a short region of double-stranded RNA and a guanosine residue which can be either free G or the 3' nucleotide of a chain. Steps one and three are completely analogous, while step two is the reverse reaction. The similarity of the substrates for the three reactions strengthens the view that the entire splicing process is catalysed by a single enzyme activity. If the substrate was defined by local sequence and structure, and not by the overall folding of the intron, it seemed likely that the enzyme might also be capable of catalysing the reaction on an exogenously supplied template. Figure 2 shows the structure of the conserved core of the Tetrahymena rRNA intron, drawn according to Davies et al.6. This segment of the intron contains the conserved P, Q, R and S sequences of Davies et al., but not the flanking secondary structures. The secondary structure of the core is supported by a considerable degree of phylogenetic comparison^{6,9}, and some structural analysis^{15,16}.

The hypothesis that this conserved core contains the enzymatic activity was tested by constructing a series of plasmids (Fig. 3) that could be transcribed in vitro by T7 RNA polymerase to yield RNA molecules that could be tested for self-splicing or trans-esterification activity. The first experiment involved the insertion, downstream of a T7 RNA polymerase promoter, of

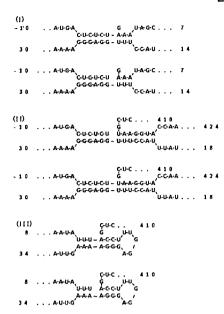

Fig. 1 Substrates for the RNA enzyme. The first transesterification reaction (I) is between a free G residue and an A residue that is part of a stem-loop structure. The double-stranded stem is formed between the exon-intron junction sequence, and the internal guide sequence^{6,9}. Release of the G-intron allows a more extensive pairing between the internal guide sequence and the 3' intron-exon sequence (II). The intron ends in G, which is placed in the same position as the incoming G in reaction I. Catalysis of the reverse reaction then results in loss of the intron and joining of the 5' and 3' exons. Circularization of the intron (III) takes place in a similar sequence and secondary structure context. The first nucleotide of the intron is +1 in the sequence coordinate system.

a DNA restriction fragment spanning the entire intron. As expected, RNA transcribed in vitro from this DNA and gelpurified was able to perform all three steps of the self-splicing process when incubated in buffer containing Mg2 guanosine. A series of RNAs truncated at different 3' positions was generated by cleavage of the DNA template with restriction endonucleases, followed by T7 RNA polymerase runoff transcription. The enzyme ScaI cuts just inside the 3' end of the intron, and templates cleaved with this enzyme yield RNA molecules lacking the 3' intron-exon junction. Remarkably, these transcripts still splice, apparently finding new acceptor splice sites within the intron sequence. The enzyme NheI cuts the DNA 20 nucleotides 3' of the conserved core, while BglII cuts within the core region. Transcription of NheI-cut DNA yielded enzymatically active RNA, as incubation of the gelpurified RNA with guanosine in splicing buffer resulted in the appearance of smaller RNA products. The RNA resulting from transcription of Bg/II-cut DNA was inert. All subsequent experiments were therefore done with transcripts of NheI-cut DNA.

The extent of 5' sequences required for enzymatic activity was determined by constructing internal deletions. Since the RNAs synthesized from these templates lack all of the sequences at which splicing normally takes place, an exogenous substrate was added to assay for trans-esterification activity. The three plasmids used to generate the shortened catalytic RNAs are shown in Fig. 3; pLG8 and pLG9 delete intron sequences to within 84 and 51 nucleotides of the conserved core (the first nucleotide of the P3 segment, GACCGUCA, in Fig. 2), while in pSZ243, all intron sequences farther than 9 nucleotides from the core are deleted. These catalytic RNAs were tested on a substrate prepared by T7 RNA polymerase transcription of pSZ241 cut with DraI. This generates a 119-nucleotide RNA containing the sequences that are the substrate for the first trans-esterification reaction (Fig. 1). The substrate RNA begins

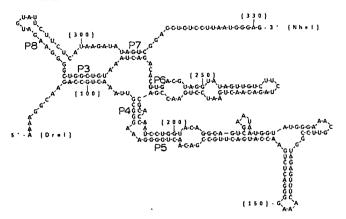

Fig. 2 Secondary structure of the conserved core of the RNA enzyme. All of the group I introns are characterized by conserved sequence elements and a conserved secondary structure. The conserved pairing regions P3, P4, P5, P6, P7 and P8 are labelled in accordance with the model of Davies et al.⁶. The nucleotide coordinates are numbered from the beginning of the intron. The segment of the Tetrahymena rRNA intron illustrated here corresponds to the T7 transcript of plasmid pSZ243 digested with NheI. Thus, reaction (I) (Fig. 1) involves the action of this catalytic core on sequences 100 nucleotides upstream, and reaction (II) involves substrate sequences both upstream and downstream from the conserved core.

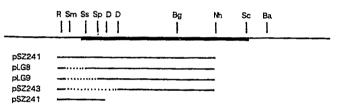

Fig. 3 Plasmids and transcripts used in the present study. The location of the intron relative to certain restriction sites is indicated by the heavy-lined segment. Plasmid pSZ241 contains the entire intron flanked by exon sequences. It was constructed by inserting the HinfI fragment of pTre1 (obtained from E. H. Blackburn) into the SmaI site of the T7 transcription vector pST53 (obtained from S. Tabor). Enzymatically active RNAs were generated by transcription of BamHI, ScaI or NheI digests of this DNA with T7 RNA polymerase. Plasmid pLG8 was generated by partial digestion of pSZ241 with SspI, complete digestion with SmaI, followed by blunt-end ligation. Plasmid pLG9 was generated by digestion of pSZ241 with SmaI and SphI, treatment with T4 polymerase to generate blunt ends, followed by blunt-end ligation. pSZ243 was constructed by blunt-end ligation of the gel-purified DraI fragment of pSZ241 into SmaI-cut pSZ241, followed by NheI digestion and recircularization. Substrate RNA was made by T7 transcription of DraI-cut pSZ241 DNA. All transcripts were purified by acrylamide-urea gel electrophoresis.

with 25 nucleotides of vector sequences, followed by 32 nucleotides of the 5' exon and the first 62 nucleotides of the intron. Activity was assayed by mixing catalytic RNA with substrate RNA in the presence of labelled GTP. The activity of the full-length intron RNA and of the three deletion derivatives was assayed (Fig. 4). All of the catalytic RNAs were able to cleave the substrate RNA at the exon-intron junction. The major labelled product is formed by the addition of GTP to the 5' end of the intron sequence. No incorporation of labelled G is observed in the absence of RNA enzyme. Since the pSZ243-NheI transcript contains only the conserved core sequence flanked by 10-20 nucleotides at each end, the conserved core does in fact contain the enzyme activity responsible for the trans-esterification reactions.

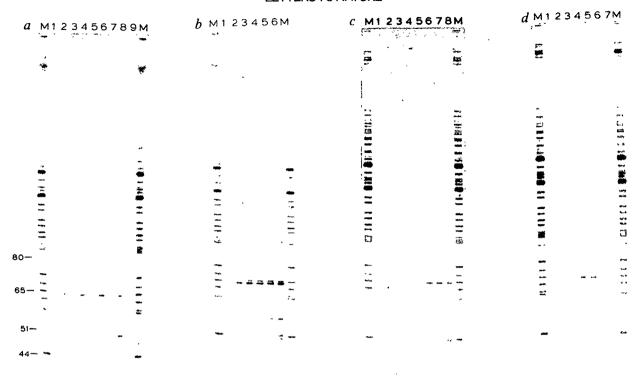

Fig. 4 Products of RNA-catalysed trans-esterification. a, Activity of deletion derivatives. Lane 1 contains substrate (transcript of DraI-cut pSZ241) but no enzyme (catalytic RNA). Lanes 2, 4, 6 and 8 contain enzyme and substrate; lanes 3, 5, 7 and 9 contain enzyme but no substrate. Lanes 2 and 3 show the addition of G and cleavage of substrate by the T7 transcript of NheI-cut pSZ241. Lanes 4 and 5 contain transcript of NheI-cut pLG8, lanes 5 and 6 contain the pLG9-NheI transcript, and lanes 7 and 8 contain the pSZ243-NheI transcript. The major product runs just below the 65-nucleotide marker, and corresponds to the GTP-intron sequence addition product. All reactions were done in the presence of 10 mM NH₄Cl, 20 mM MgCl₂, 30 mM Tris-HCl pH 7.4 and 0.2 mM aurin tricarboxylic acid. Incubations were for 30 mm at 58 °C. Catalytic RNAs were assayed at a concentration of ~50 nM, substrate RNAs were present at 0.5 μM, and α-labelled GTP at 2 5 μM. Size markers (Lanes M) are the 'A'-lane of a dideoxy-terminated sequence analysis reaction using a primer corresponding to the first 17 nucleotides of the substrate transcript, and DNA of pSZ241 as template. Sizes are 31, 32, 33, 44, 45, 48, 51, 58, 59, 60, 62, 65, 66, 68, 72 and 80 nucleotides for the region of interest. b, Time course of reaction. Aliquots were removed at 0, 15, 30, 45, 60 and 90 min (lanes 1-6) from a reaction of the enzymatically active pSZ243-NheI transcript, with α-labelled GTP and the pSZ241-DraI transcript as substrates. Reaction conditions were as for a. c, Optimal Mg²⁺ concentration. Reactions were as in b for 30 min, except that the Mg²⁺ concentration was varied. Reactions in lanes 1-8 contained 0, 2, 5, 10, 20, 30, 50 and 100 mM Mg²⁺, respectively. d, Temperature optimum. Reactions were as in b for 15 min, except that the temperature was varied. Lanes 1-7 show reactions incubated at 42, 46, 50, 54, 58, 62 and 66 °C, respectively.

The initial experiments used reaction conditions similar to those of Bass and Cech¹⁴. Characterization of the core enzyme, however, revealed some changes in optimum reaction conditions. The optimal Mg2+ concentration had increased from the 5 mM reported for the intact intron, to 20-40 mM (Fig. 4). This may reflect the difference between the intramolecular reaction of the intact intron and the intermolecular reaction, which requires a close interaction between separate substrate and enzyme molecules. This is supported by the effect of the volume excluder polyethylene glycol, which had a strong rate-enhancing effect at low Mg²⁺ concentration, but very little effect at a higher Mg²⁺ concentration. The temperature optimum of the reaction was a remarkably high 58 °C (Fig. 4), which was particularly surprising in view of the relatively short double-stranded region in the substrate stem loop and the short base-paired regions characteristic of the core enzyme itself. It is likely that the structure of the enzyme is stabilized by numerous tertiary interactions, and that the enzyme in turn stabilizes the structure of

The major products of the *trans*-esterification reaction clearly correspond to those expected by sequence-specific cleavage and GTP addition at the exon-intron boundary. Several minor products are visible, and may reflect a decreased sequence specificity of the small enzyme RNA. The identity of the major product

of the reaction was confirmed by examining the products of cleavage of 5'-end labelled RNA and uniformly labelled RNA (data not shown). The 3' fragment is not seen when 5' labelled RNA and cold G are used. With uniformly labelled RNA, the mobility of the 3' fragment is approximately 1 nucleotide faster if GTP rather than G is used as co-substrate, as expected from the extra negative charge contributed by the triphosphate moiety. The expected 57-nucleotide 5' fragment is seen with both 5' and uniformly labelled substrate RNA, but in submolar yield relative to the 3' fragment, probably because of splicing onto other substrate or enzyme sequences. In addition, other fragments are seen when labelled substrate RNA is used, possibly due to an inherent hydrolytic activity of the enzyme.

The observation that the self-splicing intron can be dissociated into an enzymatically active core and distinct substrate sequences should facilitate the genetic and biochemical analysis of both enzyme and substrate. Experiments with modified substrates should define the aspects of the substrate that are recognized by the enzyme. It should be a straightforward matter to define the minimal sequences required for enzymatic activity. Mutations in the enzyme which have specific effects on the binding of the RNA substrate or the guanosine co-substrate, or on the rate or nature of the reaction, should be informative with respect to the mechanism of catalysis. In addition, the constraints

that such information will place on enzyme structure and enzyme-substrate interactions will facilitate the development of models of the tertiary structure of the enzyme.

It is widely thought that RNA catalysis played an important part early in the evolution of life, before the evolution of protein synthesis. Sharp has suggested that early RNA replicases worked by splicing together short oligonucleotides in a template-directed manner¹⁷. An RNA polymerase-like activity of the Tetrahymena intron has recently been reported¹⁸. Mutations that lead to a loss in sequence specificity might result in a more general polymerase activity. It may therefore be possible to design an RNA replicase made of RNA by introducing a relatively small number of changes into the Tetrahymena intron core.

I thank Stan Tabor and Charles Richardson for gifts of T7 RNA polymerase, Laura Glew and Anne Gerber for technical assistance, and Andrew Murray for comments on the manuscript. This work was supported by a grant from Hoechst AG.

Mechanism of recognition of the 5' splice site in self-splicing group I introns

Gian Garriga*, Alan M. Lambowitz*, Tan Inoue† & Thomas R. Cech‡

Group I introns include many mitochondrial ribosomal RNA and messenger RNA introns and the nuclear rRNA introns of Tetrahymena and Physarum 1-6. The splicing of precursor RNAs containing these introns is a two-step reaction. Cleavage at the 5' splice site precedes cleavage at the 3' splice site, the latter cleavage being coupled with exon ligation⁷⁻⁹. Following the first cleavage, the 5' exon must somehow be held in place for ligation. We have now tested the reactivity of two self-splicing group I RNAs, the Tetrahymena pre-rRNA and the intron 1 portion of the Neurospora mitochondrial cytochrome b (cob) pre-mRNA, in the intermolecular exon ligation reaction (splicing in trans) described by Inoue et al. 10. The different sequence specificity of the reactions supports the idea that the nucleotides immediately upstream from the 5' splice site are base-paired to an internal, 5' exon-binding site, in agreement with RNA structure models proposed by Davies and co-workers^{2,3} and others^{4,5,11}. The internal binding site is proposed to be involved in the formation of a structure that specifies the 5' splice site and, following the first step of splicing, to hold the 5' exon in place for exon ligation.

When the dinucleotide CpU or pCpU is incubated with the Tetrahymena pre-rRNA, the RNA is cleaved exactly at its 3'

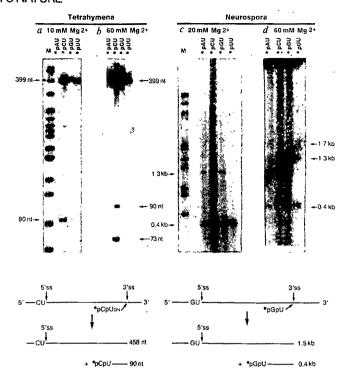

Fig. 1 Intermolecular exon ligation. Tetrahymena pre-rRNA was incubated with ³²P-pApU, ³²P-pCpU, ³²P-pGpU or ³²P-pUpU in Tetrahymena reaction conditions (10 mM Mg²⁺)(a) or Neurospora reaction conditions (60 mM Mg2+) (b). Neurospora cob pre-mRNA was similarly incubated in Neurospora reaction conditions (20 mM Mg²⁺) (c) or 60 mM Mg²⁺ (d). Tetrahymena and Neurospora reaction conditions are defined below. The diagrams at the bottom show trans-splicing reactions for Tetrahymena and Neurospora RNAs (not drawn to scale).

Methods. Tetrahymena pre-rRNA was prepared by transcription of pT7TT1A3, a phage T7 promoter version of the SP6 promotercontaining plasmid pSPTT1A3 (ref. 20). Neurospora cob intron 1 RNA was prepared by transcription of pSP64-H2a, using SP6 RNA polymerase at 40 °C in the absence of spermidine 12. Dinucleotides ApU, CpU, GpU and UpU (Pharmacia, P-L Biochemicals) were end-labelled using polynucleotide kinase and [\gamma^{32}P]ATP^{10}. Each labelled dinucleotide ran as a single band on a 20% polyacrylamide gel; the dinucleotides were not significantly cross-contaminated by this criterion. Splicing reactions were carried out by incubating 1.17 pmol of the Neurospora transcript or 0.03 pmol of the Tetrahymena transcript with 32P-pCpU, 32P-pApU, 32P-pGpU ³²P-pUpU (12 nmol for Neurospora, 0.2 nmol for Tetrahymena) for 1 h in 5 µl of reaction media. The experiment in a was carried out under Tetrahymena reaction conditions: the reaction media contained 200 mM NH₄Cl, 10 mM MgCl₂, 50 mM EPPS (N-2-hydroxyethylpiperazine-N'-2'-propanesulphonic acid)-HClpH 7.5, and the splicing reactions were carried out at 30 °C. These conditions differ somewhat from those used previously 10. The experiments in b, c and d were carried out under Neurospora reaction conditions: the reaction media contained 50 mM NH₄Cl, 20 or 60 mM MgCl₂, and 50 mM EPPS-HCl pH 7.5, and the splicing reactions were carried out at 37 °C. The reactions were terminated by addition of EDTA (100 mM), and RNAs were precipitated with ethanol three times before analysis. Tetrahymena RNAs (a and b) were analysed on an 8% polyacrylamide (20:1, acrylamide: bisacrylamide) gel containing 7 M urea, 90 mM Tris-borate, 2.5 mM EDTA. Neurospora RNAs (c and d) were glyoxalated and analysed on a 1.6% agarose gel²¹; ethidium bromide staining confirmed that equal amounts of RNA had been loaded on each lane. The gels were dried and analysed by autoradiography.

splice site and the dinucleotide is covalently ligated to the 3' exon¹⁰. This reaction can be explained as an intermolecular version of exon ligation, because it occurs with oligonucleotides whose sequence resembles that of the 5' exon (CUCUCU), and their site of attachment is identical to that of exon ligation. Except for the terminal uridine residue, the sequence preceding

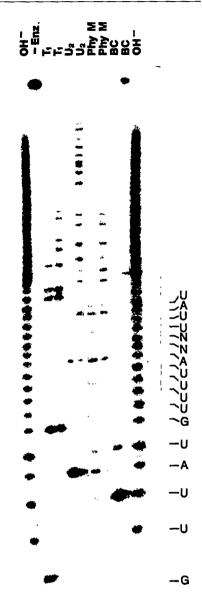

Fig. 2 RNA sequencing of the 32 P-pGpU-labelled 0.4-kb RNA. The 0.4-kb Neurospora RNA (conditions of Fig. 1d, 3 h incubation) was purified by gel electrophoresis. The RNA was then sequenced by partial hydrolysis with ribonucleases and alkali $(OH^-)^{22-24}$. Ribonuclease T_1 is specific for G residues, ribonuclease U_2 for A residues, ribonuclease Phy M for A and U residues, and Bacillus cereus (BC) ribonuclease for C and U residues. '-Enz.' shows RNA incubated under the conditions used for RNase T_1 , but in the absence of enzyme. 3'ss, 3' splice site; the boxed GU represents RNA sequencing reactions were analysed on a gel containing 22% polyacrylamide (20:1, acrylamide: bisacrylamide), 7 M urea, 90 mM Tris-borate, 2.5 mM EDTA.

the 5' splice site is not conserved among group I introns. For example, among other group I introns that have been found to be self-splicing in vitro, the first intron of the Neurospora cob gene is preceded by CUGGGU (ref. 12) the yeast rRNA intron by AGGGAU (ref. 13) and intron 5a of the yeast cytochrome oxidase subunit 1 gene by AUGAUU (refs 14, 15). If each of

these sequences defines a 5' splice site because it pairs with a sequence within the intron, the intermolecular exon ligation reaction should show a preference for oligonucleotides of different sequence. On the other hand, if the reaction of the Tetrahymena pre-rRNA with CpU reflects its interaction with one of the sequence elements that is conserved among group I introns, or some unanticipated higher nucleophilicity of CpU compared with the other dinucleotides, then CpU might be the most reactive dinucleotide towards all the precursor RNAs.

Truncated versions of the Tetrahymena pre-rRNA and Neurospora cob pre-mRNA were synthesized in vitro using either SP6 or T7 RNA polymerase. The transcripts were incubated with ³²P-labelled dinucleotides (³²P-pNpU_{OH}) under either Tetrahymena or Neurospora conditions (see Fig. 1 legend) in reaction media containing different concentrations of MgCl-Figure 1a and b shows incubation of the Tetrahymena RNA with the four labelled dinucleotides under optimal splicing conditions for that intron (Tetrahymena conditions, 10 mM MgCl₂) or under Neurospora conditions in a reaction medium containing 60 mM MgCl₂. In both cases, incubation with ¹²PpCpU resulted in labelling of a 90-nucleotide RNA band that is the product of intermolecular ligation of pCpU to the 3' exon. (Size was measured as 92 nucleotides relative to DNA markers, the size of 90 nucleotides is based on sequence of the DNA I The identity of this band was confirmed by partial digestion of the 90-nucleotide (90-nt) band with RNase T1 (data not shown) A number of other bands were also labelled, particularly under the high-Mg²⁺ conditions. The 399-nt band labelled by pCpU and pUpU was shown previously to result from reopening of the circular intervening sequence (IVS)16. The band slightly larger than the IVS labelled by pGpU and the 73-nt band labelled by pCpU under high-Mg²⁺ conditions were not observed previously with other in vitro transcripts incubated under somewhat different conditions¹⁰; their identities are unknown. Under both sets of conditions, the trans-splicing reaction showed a strong preference for pCpU. We observed no trans-splicing with pApU or pUpU, and incubation with pGpU resulted only in very inefficient labelling of a band of ~90 nt (<5% of the reaction with pCpU; Fig. 1a).

Trans-splicing of the Neurospora RNA showed the different specificity predicted for the interaction between the dinucleotide and the putative 5' exon-binding site. Figure 1c and d shows incubations of the Neurospora RNA with the four labelled dinucleotides in solutions containing 20 mM MgCl, and 60 mM MgCl₂, respectively. In both reaction media, incubation with pGpU gave a prominent labelled RNA of the size expected for the 3' exon (0.4 kilobases (kb); Fig. 1c,d). The identification of this RNA as the trans-splicing product is confirmed below. We observed no trans-splicing with pCpU, which is the most reactive dinucleotide for the Tetrahymena RNA. However, incubation with pApU and pUpU gave about 10% and 20%, respectively, of the extent of reaction with pGpU. The relative reactivities of the four dinucleotides in the putative trans-splicing reaction were roughly the same in reaction media containing 10, 20, 30 and 60 mM Mg²⁺. Considered together, the results show that the Neurospora trans-splicing reaction has the specificity predicted for base pairing with the 5' exon-binding site, but that the specificity appears to be somewhat less stringent than that for the Tetrahymena RNA. The trans-splicing reaction for Neurospora RNA also seems to be less efficient than that for the Tetrahymena RNA and requires higher concentrations of precursor RNA and dinucleotide (see Fig. 1 legend) The inefficiency of the specific reaction with pGpU necessitated loading more RNA per lane, which may make competing reactions with pApU and pUpU appear more prominent. We note, however, that pCpU shows no trans-splicing reaction whatsoever, indicating that this dinucleotide must be somehow incompatible with the exon-binding site.

To confirm that intermolecular exon ligation had in fact occurred for the Neurospora RNA, the 0.4-kb RNA labelled by

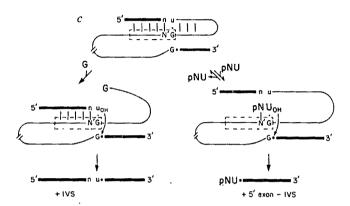

Fig. 3 Internal binding site model accounts for the sequence specificity of the exon ligation reaction. Structures of N. crassa cob pre-mRNA¹² (a) and T. thermophila pre-rRNA^{3,5} (b) are shown. Lower case letters, exons; capital letters, introns; •, 3' splice site. Boxed nucleotides indicate the portion of the internal guide sequence proposed to pair with the 5' exon^{2,3}. The pairing of the 3' exon with an adjacent portion of the internal guide sequence, which is not supported by mutation analysis²⁵, has been omitted from the diagrams. The interaction that holds the 3' splice site in place is therefore left unspecified. c, Generalized model for the role of the internal binding site. Left, normal exon ligation; right, intermolecular ligation of dinucleotides. The dinucleotide competes with the 5' exon of the intact precursor RNA for binding to the internal guide sequence. When the dinucleotide binds, its free 3'-hydroxyl group is directed towards the phosphorus atom of the phosphate at the 3' splice site in such a way as to facilitate nucleophilic attack. The result is covalent attachment of the dinucleotide to the 3' exon, an intermolecular version of exon ligation.

³²P-pGpU was purified and its sequence determined as shown in Fig. 2. The sequence confirmed that ³²P-pGpU had become covalently attached to the 3' exon by a phosphodiester linkage. The sequence of the 3' exon was the same as determined by Helmer-Citterich et al.¹⁷ and Burke et al.¹⁸.

Incubation of the Neurospora RNA with all four dinucleotides resulted in labelling of two larger bands of 1.7 and 1.3 kb, in addition to the 0.4-kb band. These larger bands are more prominently labelled under the high-Mg2+ conditions (Fig. 1c,d). Their sizes are those expected for the excised intron (1.3 kb) and intron plus 3' exon (1.7 kb). Because Neurospora cob intron 1 was not observed to undergo cyclization under any conditions tested previously¹², labelling of an intron-sized RNA by circle reopening16 was not anticipated. One possibility, therefore, is that labelling of the 1.3- and 1.7-kb bands reflects inefficient selfsplicing initiated by the dinucleotide substituting for the normal guanosine cofactor. The Tetrahymena RNA has been reported to show inefficient splicing with nucleoside triphosphates other than GTP9. Again, these competing reactions may appear more prominent here because of the inefficiency of the trans-splicing reaction with the Neurospora intron.

In the previous study of trans-splicing with the Tetrahymena intron, the two trinucleotides tested, UCU and UUU, had the

relative reactivities predicted for base-pairing with the putative 5' exon-binding site 10. In analogous experiments, the trinucleotides GGU, AGU and GAU were tested with the Neurospora RNA, and in each case the extent of reaction was greater than with the dinucleotide GU (data not shown). The increased reactivity of GGU might be explained on the basis of increased base-pairing interactions with the active site, while the reactivity of the other two trinucleotides might be explained as a combination of base-pairing and increased base-stacking interactions. Any such interpretation was clouded, however, by the unexpected finding that in 10 mM MgCl₂ the Tetrahymena RNA reacted efficiently with GGU and GAU, and to a smaller extent with AGU, to give RNAs of the size expected for trans-splicing to the 3' exon (91 nt). Partial RNA sequence analysis with RNase T₁ confirmed that GGU was accurately spliced to the 3' exon (data not shown). Thus, although Watson-Crick base-pairing with the 5' exon-binding site may be an important determinant of the trans-splicing reaction, additional interactions must also contribute to determining the extent of reaction with trinucleotides. Base stacking or non-Watson-Crick hydrogen-bonding might allow certain trinucleotides to interact with the normal binding site. Alternatively, the trinucleotide might interact with other, at present unidentified, binding sites within the intron.

Although the findings for trinucleotides were unexpected, our results show that Neurospora cob intron 1 RNA, like the Tetrahymena RNA, undergoes a specific trans-splicing reaction with dinucleotides. If the ligation of dinucleotides to the 3' splice site is an intermolecular version of exon ligation, then each precursor RNA should show the greatest reactivity with the dinucleotide whose sequence is homologous to that of the 3' end of its 5' exon. This prediction is satisfied by the relative reactivity of the Neurospora pre-mRNA with pGpU compared with other dinucleotides and of the Tetrahymena pre-rRNA with pCpU compared with other dinucleotides.

The relative reactivities of the different dinucleotides is most easily explained if each intron contains an exon-binding site that is complementary to the last two nucleotides of its own 5' exon. This requirement is fully met by the internal guide sequence model of Davies et al.². The internal guide has a different sequence in each intron, but a portion of the sequence is always complementary to the 6 or so nucleotides in the 5' exon immediately preceding the intron. The only conserved nucleotide is a G in the internal guide which pairs with the conserved U at the 5' splice site. Similar structural models incorporating the 5' exon-internal guide sequence pairing have been proposed by Michel et al.^{4,5} and Bos et al.¹¹.

Figure 3 shows the proposed mechanism by which the internal guide sequence promotes the intermolecular exon ligation reactions. The 5' exon is bound to the internal guide, but in the absence of cleavage by guanosine the exon does not have a free 3' hydroxyl group, so it cannot attack the 3' splice site. When the dinucleotide transiently displaces the 5' exon, its free 3' hydroxyl group attacks the 3' splice site.

In the normal exon ligation reaction, the 5' exon-binding site is proposed to serve two functions. It is responsible for choice of the 5' splice site, that is, the site at which free guanosine or GTP attacks. Thus, the guanosine-binding site¹⁹ must be in a fixed position relative to the 5' exon-binding site, perhaps by way of a direct interaction⁹. In addition, the binding site orients the 5' exon in proximity to the 3' splice site, helping to lower the activation energy for the exon ligation reaction. It therefore helps to determine the accuracy of reactions at both the 5' and 3' splice sites.

Recently, site-specific mutagenesis studies have confirmed that the sequence GGAGGG at nucleotides 22-27 of the *Tetrahymena* intron is the 5' exon-binding site^{26,27}.

We thank S. Walstrum and O. Uhlenbeck (University of Colorado) for their gift of trinucleotides. This work was supported by NIH grant GM26836 to A.M.L. and by NIH grant GM28039 and American Cancer Society grant NP374B to T.R.C.

Intermolecular binding of xanthan gum and carob gum

P. Cairns, M. J. Miles and V. J. Morris

AFRC Institute of Food Research, Norwich Laboratory, Colney Lane, Norwich NR47UA, UK

Gels are a representative state for polysaccharides in both natural and retificial systems. The nature of the inter-chain associations within the junction zones is important and models for such interactions between like polysaccharides are based on X-ray diffraction studies of oriented gels. Here we describe the extension of such studies to a binary gel (xanthan-carob) in order to characterize for the first time intermolecular binding between different polysaccharides. Xanthan-carob binding has been proposed to explain gelation of the mixtures and as a model for host-pathogen recognition and adhesion of Xanthomonas bacteria within plant vascular systems. Our data suggest that the established model 1-7 is incorrect and point to an alternative association mechanism.

Xanthan has a repeat unit^{8,9} based on a cellulose backbone with alternate glucose residues O-3-substituted with a trisaccharide side chain. Carob has a mannan backbone that is incompletely O-6-substituted with galactose² and a mannose/galactose ratio of 3.55 (ref. 10). Xanthan-carob binding is postulated to involve a mixed cooperative interaction in which the xanthan helix is retained (Fig. 1). We tested this model by X-ray fibre diffraction studies of oriented xanthan-carob gels, since this is

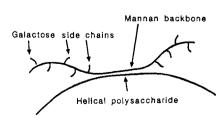

Fig. 1 Schematic diagram of the proposed binding of the xanthan helix to the bare mannan backbone of the galactomannan carob. Analogous models have been proposed¹⁻⁴ to explain the interaction between galactomannans and certain algal polysaccharides.

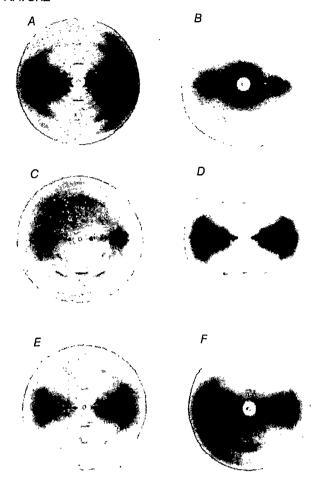

Fig. 2 X-ray fibre diffraction patterns recorded for polysaccharides and polysaccharide mixtures. Gels were cut into strips and stretched to induce alignment. Non-gelling mixtures were cast onto glass or PTFE substrates, dried to films, cut into strips and aligned by stretching. The X-ray wavelength was 0.154 nm; the camera was flushed with helium to reduce scattering. Pictures were calibrated with calcite. A, Xanthan, stretched 300%; B, carob, stretched 300%; C, carob, stretched 300% and stored at room temperature for 3 yr; D, mixed gel: 25% xanthan/75% carob, stretched 300%; E, mixed gel: 50% xanthan/50% carob, stretched 300%; F, non-gelling mixture: 50% xanthan/50% carob, prepared at room temperature, stretched 100%.

the only method available to examine polysaccharide ordered structures at atomic resolution and has provided reliable models for structures in the hydrated state¹¹.

Under conditions appropriate for studying fibres prepared from mixed gels, pure xanthan and carob gave the fibre patterns shown in Fig. 2A, B. Storage of carob fibres enhanced crystallinity (Fig. 2C). Diffraction data obtained for fibres prepared from xanthan-carob mixed gels are shown in Fig. 2D, E and these new X-ray patterns provide evidence for xanthan-carob binding.

Optical rotation measurements are sensitive to the helix-coil transition¹² and were used to monitor helix formation in xanthan samples. Thorough mixing of carob with xanthan in the helical conformation at room temperature did not lead to gelation. X-ray diffraction data on fibres prepared from such mixtures (Fig. 2F) showed reflections characteristic of pure xanthan (Fig. 2A) with no evidence of carob crystallization or carob-xanthan co-crystallization. Gelation only occurred when these mixtures were heated (95 °C) above the xanthan helix-coil transition temperature (T_c) and then re-cooled to room temperature. Oriented gels yielded fibre patterns of the type shown in Fig. 2D, E. T_c is particularly sensitive to the presence of divalent cations

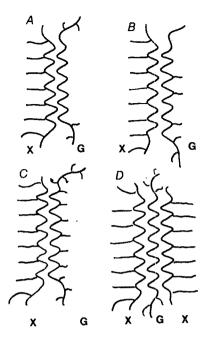

Fig. 3 Schematic representation of possible xanthan (X)-galactomannan (G) binding. Possible binding between a xanthan backbone and: A, bare mannan regions of the galactomannan backbone; B, randomly substituted galactomannan; C, galactomannan containing galactose on alternate mannose residues. D, Simplest xanthan-galactomannan sandwich structure.

in the medium¹³. When carob was mixed with xanthan in the presence of sufficient calcium chloride such that $T_c > 100$ °C, and the samples were heated (95 °C) and re-cooled to room temperature, they did not gel; this suggests that denaturation of the xanthan helix is necessary if intermolecular association and gelation is to occur. Glucose and mannose differ only in the orientation of the hydroxyl substituent at C-2, suggesting the possibility of binding between the sterically compatible cellulose backbone of xanthan and the mannan backbone of carob.

Optical rotation studies¹⁴ on xanthan-galactomannan mixtures coupled with enzymatic studies¹⁵ on xanthan-carob mixtures suggest that only small segments of both backbones could be involved in binding, with the remaining xanthan reforming the helical conformation. Alignment of mixed junction zones will also lead to alignment of xanthan helices. Thus, reflections characteristic of aligned xanthan should be neglected in Fig. 2D, E in order to characterize the mixed junction zone. The first meridional reflection for the mixed junction zones corresponds to an interplanar spacing of 0.52 nm, characteristic of cellulose¹⁶ or mannan¹⁷, supporting binding between the backbones but ruling out simple binding schemes of the type shown in Fig. 3A-C. To achieve the correct interplanar spacing appropriate to the first meridional reflection, it would be necessary to stagger the positions of the xanthan side chains (Fig. 3D) although the stoichiometry of such sandwich structures is undefined. The mixed junction zone patterns are equivalent to carob patterns for which only 0kl reflections are allowed. The simplest answer would be to permit growth of a sandwich structure in the b and c directions but to restrict growth in the a direction. However, streaking of layer line reflections characteristic of such laminar structures was not observed. The alternative is to envisage a structure periodic in the b and c directions but aperiodic in the a direction.

The data presented here constitute the first example of a conformational modification of one polysaccharide by a noncovalent interaction with another polysaccharide. The structural similarity of the xanthan and carob backbones accounts for the

specificity of the interaction and also explains why X-ray diffraction studies 10,18,19 have failed to reveal proposed 1-7 intermolecular binding between galactomannans and the structurally incompatible algal polysaccharides k-carrageenan and furcellaran. The data support suggested co-crystallization of cellulose with galactomannans²⁰ or xyloglucans²¹⁻²³ in complex plant cell walls. Binding of extracellular xanthan to plant cell wall components is only likely if helix formation is incomplete. This cannot, however, exclude possible host-pathogen interactions because such extracellular assembly is normally biochemically controlled.

Imaging cells with acoustic microscopy

from M. Issouckis

The interaction between the mechanical waves of scanning acoustic microscopy (SAM) and the mechanical features of living cells makes a novel contribution to the characterization of biological materials.

High resolution scanning acoustic microscopy, or SAM, provides an opportunity to investigate the microstructure of materials on, and under, the material surface. In biology, acoustic imaging of living cells, mucous coats and cuticle structures has been very successful. The imaging of these biological objects has been described by M. Hoppe and J. Bereiter-Hahn¹. This paper uses their work with living cells as a springboard for discussing high resolution SAM and SAM image interpretation in the life sciences.

The heart of the high resolution SAM (Fig.1) is its lens assembly. A focused ultrasound wave (of frequencies between 1 and 2 GHz), generated by means of a pizoelectric transducer, is used to probe the sample. This same transducer receives the reflected wave, which is subsequently processed. By scanning in a roster fashion, an image is formed that represents the interaction between the acoustic material and the elastic properties of the sample material.

Some requirements of SAM imaging impose limitations on the types of samples that can be studied. As in high resolution light microscopy, high resolution SAM requires lenses with short focal length. Consequently, the depth of focus is small. In addition, attenuation (absorption) of acoustic waves by the intermedium limits the distance between lens and specimen.

These features restrict the application of acoustic microscopy to very small objects; that is, those that are very flat and in a plane parallel to the scanning plane of the acoustic lens. Flat structures such as insect wings and scales, and cells attached to glass or any other planar surface, fulfil these conditions.

Although observations of cell or organelle damage by ultrasound have been reported for lower frequencies (20 kHz, 5 MHz)^{2,3} damage to living cells does not occur with gigahertz frequencies. Experiments have shown that after more than one hour's exposure to 1 GHz ultrasound, sensitive epidermal cells still exhibit normal locomotive behaviour. These findings are consistent with theoretical expectations, which predict a decrease in cell damage as frequencey increases because the amplitude of particle displacement induced by a longitudinal wave is limited by the wavelength.

Interpretation

Some properties of SAM can also confound image interpretation. Images of biological samples, in particular, often

show interference lines due to the substructure supporting the sample. In materials science applications, the smooth surface of a specimen represents the structure that is to be investigated. In the case of biological objects, however, the samples are located on a planar surface to which they adhere.

This situation complicates the interpretation of acoustic images by producing

on the incompressible interior cytoplasm8,9.

The mechanical properties and surface profiles of living cells result from the interaction of elements of the cytoskeleton with each other, with the cell membrane, and with the supporting substratum. Microtubules and stress fibres stiffen the cytoplasm and, together with adhesion to a substratum, cause deviations of cell shape from a sphere. This model allows an

Fig.1 An Ernst Leitz scanning acoustic microscope (ELSAM) in its commercial configuration.

interference between the waves reflected at different interfaces. These interfaces include the surface of the substratum, the medium-facing surface of the cells and, depending on the distance of a cell to the substratum, the substratum-facing cell surface.

Comparable relations are found in reflection-contrast microscopy⁴⁻⁷. Light reflected from separate interfaces causes a pattern of interference lines. The pattern indicates the surface curvature of cell at the medium-facing surface and at the surface opposed to the substrate. In this case, optical path differences that determine the course of the interference lines depend on refractive indexes and the thickness of the layers between interfaces.

Similarly, with the scanning acoustic microscope, layer thickness and acoustic impedance (which corresponds to the refractive index in optics) govern the interference pattern. But whereas light absorption is negligible in most living cells, attenuation can contribute considerably to image formation in SAM.

The internal structures of cells can also alter image generation by reflection and scattering. In general, an animal cell can be considered as a hydraulic system enclosed by a semipermeable membrane to which a contractile fibrillar system (containing actin and probably myosin) is linked. This system exerts some pressure

understanding of acoustic images of living

Mechanical disturbances by the scanning movement of the SAM lens and flow of the interconnecting medium, which are caused by sound emission in the cavity of the lens, loosen the contact of cells to a substratum. In those cells that withstand this stress, density in stress fibre arrangement is enhanced considerably.

Internal reflections

In the images of Xenopus heart cells (Fig. 2), stress fibres are clearly shown as arcs near the periphery of the cell. The dark circles concentric with the nucleus. The difference in contrast between the sample mounted on plastic (top panel) and the sample mounted on glass (bottom panel) is apparent.

The peripheral region of the plasticmounted cell is relatively flat; its thickness is approximately $\lambda/2$ at the outer dark interference ring, increasing to about $\lambda/4$ in the outer bright region. For these estimations a phase shift of $\lambda/2$ at the interface to the medium with higher acoustic

impedance is considered.

The small distances between central interferences indicate an increased slope; that is, the thickness of the sample increases in the region. The contrast of an interference line may vary considerably throughout its course, so that a dark line may

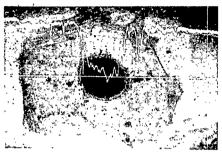

Fig.2 SAM images of endothelial cells from Xenopus laevis tadpole hearts (XTH-2 cells) using ×625 magnification and a frequencey of 1.6 GHz. The image width is 200 µm. Top panel: a sample mounted on plastic gives an interference image with stress fibres and cell topography clearly visible. The contrast of the cell fringes is related to stiffness conferred by intracellular structures. Bottom panel: a sample mounted on glass gives a more poorly defined attenuation image.

become very faint at some points (Fig. 2). However, this is not caused by a local thickness change, but by locally diminished reflectivity.

The structural basis for this reduced reflectivity is a weakened stiffness, visualized by the low contrast that is due to a diminished elastic modulus of the cortical cytoplasm. At this "weak region" the membrane can bulge out, and a thickening appears. The dark interference fringe close to the cell margin increases in contrast, indicating higher reflectivity.

The complexities posed by interference and contrast changes make SAM image interpretation a challenging task, but the information that can be gleaned from this complexity makes scanning acoustic microscopy a valuable technique for exploring the substructure of the smallest unit of life.

Setting the stage for microscopy

A collection of instruments and accessories for microscopy and image analysis closes with immunology product selections.

JEOL is offering a scanning electron microscope at a price that is more typical of advanced optical models (Reader Service No. 100). The T100, a compact and relatively simple instrument, is aimed at

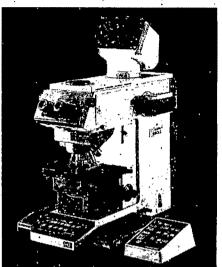

Micrographs from Jeol's new 'scopes. Rape pollen, top panel; control blood, bottom panel.

laboratories engaged in medical or botanical research and sold for £15,000 (UK). Image contrast and brightness controls are available along with a fast scan facility for TV viewing. The T100 features a single magnification adjustment that spans ×15 to ×100,000 with electronic readout. Equipped with several information channels, Jeol's microscope can be fitted with attachments for elemental analyses such as characteristic X-rays and cathodoluminescence.

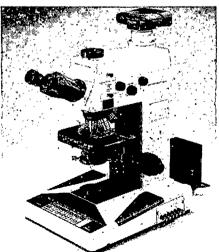

photomicrographic microscope system for research goes under the name of the New Vanox S/T from Olympus (Reader Service No. 101). Olympus says it has provided the Vanox with a flexibility that allows a wide variety of uses. The instrument has LB series objectives for super widefield observation; the eyepiece field number reaches 26.5. A motorized revolving nosepiece will alternate between six objectives at the touch of a button, whilst Köhler illumination shifts the lighting for the range of magnifications between ultra-low and high magnifying objectives. Four photographic eyepieces | The Microphot design for photomicrography.

Olympus makes flexibility its forte.

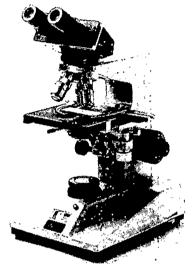

supply magnifications between 2.5× and $5\times$. Olympus designed its £18,000 (UK) machine with a rotatable stage for proper specimen alignment, and a light intensity control system based on ND filter conversion maintains constant colour temperatures regardless of light intensity.

The Microphot-FX, Nikon's new photomicrography system, combines the optical performance of the CF Plan Apocromat and Achromat series with versatile photomicrography (Reader Service No. 102). Nikon says the new instrument has 1 per cent spot or 30 per cent average exposure measurement switching, direct light measurement, direct image projection, and movable measurement area. The Microphot is also available with the

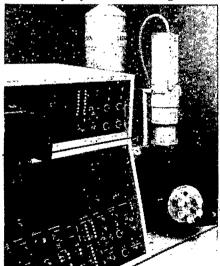

photographic attachment as an option, when photomicrography is a secondary purpose. Nikon also make several optical accessories as options, including phase contrast, diascopic fluorescence and interferometry equipment.

Straight from West Germany, an expanded range of Zeiss microscopes is being distributed by Gallenkamp in the United Kingdom (Reader Service No. 103). The company now includes "budget priced" stereo and compound microscopes, as well as more sophisticated instruments from the manufacturer. Microscopes for student work and routine research applications have been added to

Zeiss technology in the UK via Gallenkamp. the list. Gallenkamp claims its new selection is ideal for biological and materials examination.

Joining Philips' display at Micro '86 will be the company's latest scanning electron

microscope, the 525M (Reader Service No. 104). The SEM 525M, part of a field of multi-purpose microscopes, offers a large specimen chamber and motorized stage with six-inch movement. Philips will | The flow cytometer for stationary cells.

also have on exhibit the CM10, a microprocessor-controlled transmission electron microscope. The system operates through a small VDU with a divided screen and soft-key controls. An energydispersive analyser set-up called EDAX PV 9900 will also make an appearance at the conference.

A sharper image

For full colour image analysis, Analytical Measuring Systems has a semi-automatic

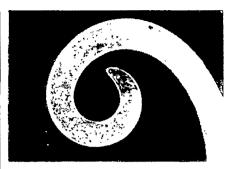

AMS has analysis in full colour.

system with software that runs on IBM PCs or compatibles (Reader Service No. 105). The VIDS III Colour uses a threegun video camera to obtain micro- or macroscopic sample images, and according to AMS, is particularly well-suited to applications in histology, cytochemistry and mineralogy. The VIDS III software can measure features within the images that are designated using a graphics tablet.

A fluorescence analysis workstation from Meridian Instruments can perform quantitative analyses of anchoragedependent cells without disturbing sterile conditions (Reader Service No. 106). Meridian's ACAS 470 system employs computer control and x-y stage positioning to direct a focused laser beam. Whilst

A spiral nematode posed for this photomicrograph, which won the Nikon Small World competition in 1985. (Reader Service No. 107). Nikon's annual contest is international and open to anyone interested in photography through microscopes. Both subject matter and microscopy technique are unrestricted. Past winners have come from disciplines as diverse as marine science and dentistry. This year's deadline was 27 June, but it is not too early to be eveing up the 1987 competition. Twenty contestants will receive awards, with the first place photographer winning a \$3,000 vacation or the equivalent in Nikon equipment. Last year's winner, who captured the image above, was J.D. Eisenback from Blacksburg, Virginia.

preserving cell attachment to extracellular matrix, the beam carries out optimal fluorescence excitation, cell sorting by laser ablation or physical separation on film, cell surgery and photobleaching of discrete areas. The workstation can also perform automated repetitive analysis on single cells or fields of cells.

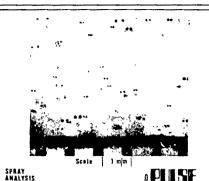

Quantel is exhibiting a high-speed digital image processing device at Micro '86 that it says can improve the contrast and

Making images CRYSTAL clear.

sharpness of images to analytical quality in real-time (Reader Service No. 108) Quantel calls its system CRYSTAL and claims the instrument can increase through-put as well as statistical validity CRYSTÂL also includes a second framestore for a reference image that can be compared to the sample input image in real-time. Quantel says CRYSTAL's features are beneficial in the inspection and analysis of non-conducting specimens. The £15,500 (UK) system is effective with ion beam, scanning optical and scanning microscopes as well as electron microscopes.

Polyscan is a fully automatic image analyser with flexible software control (Reader Service No. 109). Reichert-Jung

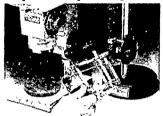

'PULSE' instrumentation equipment will produce time separated images of sprays and aerosols as

Processing by Polyscan can be customized.

developed the system with an extensive image processing library that enables customized programs to be constructed using a program editor. Polyscan accepts inputs from microscopes, video tape recorders, photometers and photographs and uses synchronous network architecture for real-time processing. For complex images, the system also allows semi-automatic measurement via a cursor-controlled digitizer.

Digithurst Ltd makes non-contact measurement and image analysis packages that perform data processing with standard microcomputers such as the IBM PC (Reader Service No. 110). The company's range can accommodate most types of microscopes, with camera mounts for optical microscopy. Digithurst's Micro-Scale software directs the detection of cell boundaries and outlines, growth rate determinations and measurements including area, length, counting, orientation to field and minimum and maximum diameters. A MicroStat statistics package provides derivation of statistical results and graphical presentation.

Joyce-Loebl introduced an image analysis system earlier this year called µMagiscan that will be displayed at Micro '86 (Reader Service No. 111). The package is based on a modified IBM PC, with software composed of test, analysis and statistics routines. The µMagiscan analysis

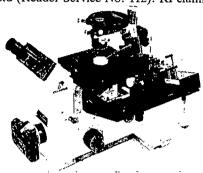

Joyce-Loebl's analyser takes on new

menu is capable of establishing working conditions, pre-processing to optimize the image state and detecting, selecting and measuring designated objects. Joyce-Loebl combined several hardware features to create µMagiscan, including a colour graphics adaptor board, a 10 MB Winchester disk and a Microsoft Mouse. The total µMagiscan package sells for less than £15,000 (UK) and consists of the computer, graphics boards, colour moni-

tor, camera, mouse, software and an Epson printer.

Microtools

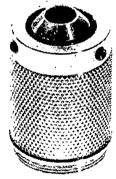

Inverted microscopes such as the Olympus IMT-2, the Nikon Diaphot and the Zeiss IM35 are the targets for a micromanipulator from Research Instruments Ltd (Reader Service No. 112). RI claims

micromanipulator that specializes in inversion.

that the TDU500 is the first leveroperated micromanipulator to use flexural hinges in its fine movement. According to the company, these hinges can provide sub-micrometre positioning accuracy. The instrument has a single lever for x-y-z fine movement, and levels for coarse x, yand z motion. Toolholders for one or two microtools are available on different TDU500 models.

Landmarks aren't easy to find under magnification, so EBETC Corp sells a \$63 (US) slide marker that puts an inked ring on slide locales that need to be identified (Reader Service No. 113). The ring is

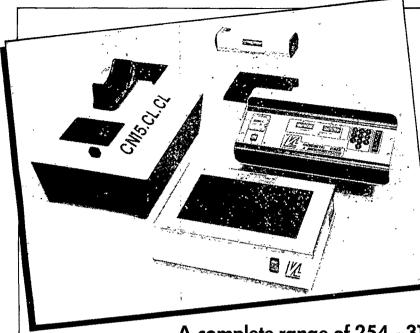

EBTEC marks the spot on microscope slides.

repeatable and concentric with the optical axis; marking will not break or damage slides. EBTEC's device fits any standard optical microscope with RMS objective thread, and the mark can be removed with solvent. EBTEC calls the marker "indispensible" for cytology, pathology, industry electron microscopy and applications.

Immunology addendum

Using plate electrodes to generate a uniform field, an electrophoretic blotting apparatus from Idea Scientific will execute Western blots in 30 minutes (Reader Service No. 114). Idea's GENIE has titanium

– NEW EDITION –—

INFORMATION SOURCES IN BIOTECHNOLOGY, 2nd Edition **Anita Crafts-Lighty**

"This book is a model. As such it should be in the hands of every librarian and information officer..." Process Biochemistry

"...very useful. No comparable work is available." Choice

First Edition—Choice Outstanding Academic book 1984-5

Revised and updated throughout, this new edition provides even more practical, incisive evaluations of both the traditional and more elusive sources of information in biotechnology. It will bring you right up to date by systematically and critically reviewing the many different sources available in:

 Trade and research literature
 Market surveys
 Company directories
 Conference Reports • Secondary sources—abstracts, title lists, indexes, bibliographies

PLUS—Greatly expanded sections on • Conference proceedings • Reading lists of introductory books • New information on • international organizations • Books out of print • How to set up and run information services • What is available for those seeking state-of-the-art coverage

A full index of publishers and addresses is included.

320pp \$100.00 0-943818-18-4 August 1986 £50.00 0-333-39290-6

plates coated with a thin layer of platinum which can blot gels up to 17 cm long. The GENIE also features an insertable loading tray that the company says will help achieve bubble-free loading. Idea's

The uniform field theory comes to electrophoresis.

machine requires less than one litre of buffer. Another version is available for gels up to 32 cm long.

Becton-Dickinson has recently released a new monoclonal antibody for B cell studies (Reader Service No. 115). The antibody, called Anti-Leu-16, reacts with an antigen found on human B cells in peripheral blood, tonsil and lymph node tis-

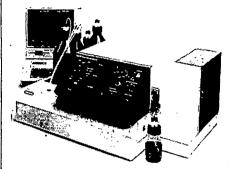

Becton-Dickinson's tool for trailing B cells.

sue. The antigen appears on approximately 10 per cent of peripheral blood lymphocytes, according to B-D. The company also says Anti-Leu-16 will not react with T cells or granulocytes and exhibits marginal reaction with monocytes. Available in purified form or as a fluorescein or phycoerythrin conjugate, the antibody can be used for B cell enumeration in peripheral blood, B cell isolation and studies of B cell neoplasms and activation.

Erratum: streptavidin pricing

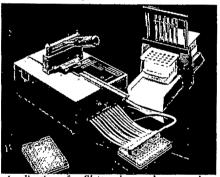

A review published in the 29 May issue of *Nature* (Vol. 321, p. 543) gave an incorrect price for Porton Products Ltd's streptavidin. In the United Kingdom, the chemical costs £5 per 0.5 mg, not 100 mg as previously stated. Porton Products sells streptavidin in 100 mg quantities for £1,000.

The latest version of Bio-Rad's MAPS (Monoclonal Antibody Purification System) kit has been designed specifically

MAPS dedicated to particular purifications.

for the purification of mouse IgG from ascites fluid (Reader Service No. 116). The kit, called Affi-Gel Protein A MAPS II, consists of protein A with MAPS buffers optimized for binding, elution and regeneration. Bio-Rad says the binding buffer increases the protein A-agarose capacity for IgG from less than 1 mg per ml to 6 to 8 mg per ml of gel. The elution buffer, the company claims, gives quantitative elution of bound IgG, and the regeneration buffer provides for up to 12 cycles. The entire kit contains the materials necessary to purify 500 mg of murine antibody.

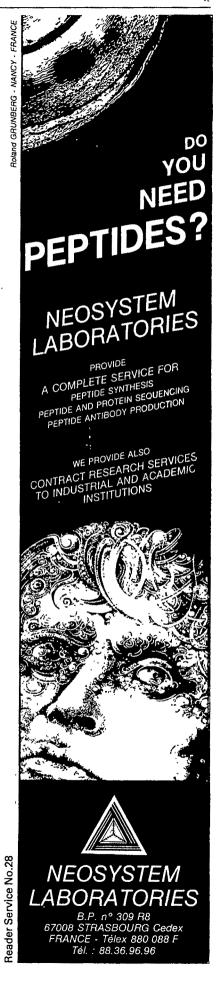

Applications for Skatron's new harvester keep growing.

Skatron is promoting a new cell harvester as an aid in receptor binding studies (Reader Service No. 117). The company describes a procedure that is intended to reduce the time and costs involved in filtration and reduce the levels of nonspecific binding. With Skatron's instrument, twelve incubation samples can be simultaneously filtered under reduced pressure. Another component, the Filterpunch, transfers the filter disks six at a time to scintillation vials. Skatron's cell harvester can also be employed in studies of HTLV-III/LAV infections.

These notes are compiled by Karen Wright from information provided by the manufacturers. To obtain further details about these products, use the reader service card bound inside the journal.

Prices quoted are sometimes nominal and apply only within the country indicated.

Will industry support higher education?

from Richard Pearson

Since 1980, government support for UK universities has dropped by over 11 per cent in real terms. Can new initiatives from industry soften the blow?

In the United Kingdom, higher education is now halfway through a decade of declining expenditure. Caught by the twin pressures of an attack on public expenditure and the reducing size of the population of 18-year-olds over the period to 1996, the University Grants Committee (UGC) and National Advisory Board (NAB) are trying to organize and manage a cash-constrained and reducing system. Overlaying these problems is the increasing pressure for higher education to become more directly relevant to the needs of the economy and increase the share of expenditure going to the 'vocational' disciplines, and engineering and technology in particular. Yet not only has this switch to higher cost courses got to be made within a shrinking budget but the physical infrastructure has also to be brought up to date with increasingly expensive technology which itself can often become obsolete within a few years.

Last year the Organization for Economic Cooperation and Development (OECD) reported on the problem of an "ageing infrastructure" and obsolete equipment in many OECD countries1. For twenty years, funding allocated for research has not matched the needs of the research community, and since the 1970s the cost of equipment has grown at a rate of 4 per cent above the inflation rate. In the United States it was estimated in 1982 that at least \$1,000 million was needed to bring university research equipment up to date. Many universities there now look to industry for help, and the tax regime makes donations tax deductable for companies. Although the majority of research and development funds for universities still come from government in one form or another, private industry has increased its spending on academic research and development by some 80 per cent since 1980 while government support has risen by only 34 per cent. It was estimated that US industry provided \$400 million to university research and development in 1984. Corporate motivation is clear: such investment aids graduate recruitment and gives access to teaching and research staff and facilities - all tax deductable. Several new university-based research centres have been established in recent years, such as that at Stanford, where 20 companies each paid \$750,000 towards new buildings, and then \$100,000 annually for three years to support education, research and administration. New centres have also opened in Texas and North Carolina. Other ventures involve consortia of small companies, while others have matching state support.

In the United Kingdom the government sees this model as one way in which higher education can ease its funding problems. In 1985 it made available an additional £43 million under the 'Engineering and Technology programme' to provide an extra 5,000 undergraduate places in information technology and related subjects in the universities and polytechnics. A condition of part of that funding was that the recipient institutions should raise significant industrial support. In the event, assistance valued at over £24 million was forthcoming in the form of equipment donations, project work, student sponsorship, research and teaching by industrial staff. Industrial support is also given to many other courses and institutions, although it is impossible to assess the total contribution in the United Kingdom with any accuracy. In addition to this direct support for higher education, there is a growing programme of collaborative activities under national and international research programmes such as Alvey and Esprit, and those more directed at training, such as CASE awards and the Teaching Company Scheme administered by the UK Science and Engineering Research

The majority of such links are negotiated at a personal level between individual academics and research or training staff in industry. As such, links have in the past developed on a very ad hoc basis. Now a number of major UK companies are seeking to develop corporate policies towards their support for higher education and are appointing 'campus coordinators' to draw together the company's activities with individual institutions in a more coherent way. They are still, however, a comparative rarity. While most collaboration is still on a one-off basis, with 'donations' often taking the form of payments in kind, there are some notable new jointly funded centres, such as the Leicester Biocentre which is funded by a consortium of companies to carry out fundamental research in biotechnology, and the recently announced Information Technology Institute organized by Cranfield Institute of Technology and supported by £4 million from over 20 high-tech companies. It is to be a commercial research and training centre running both short courses and degree programmes. The most common form of industrial collaboration remains, however, the provision of project work for students.

There is a growing interest in collaboration in both higher education and industry, and a recent survey of information technology departments showed that 86 per cent wanted to increase the level of collaboration, the remainder being satisfied with their current activities. Ironically, a 'lack of academic staff and time' was acting as a constraint to increasing the level of collaboration in two out of three departments, yet such collaboration is seen as an essential way of boosting resources. There were also concerns by one in three departments that there was a lack of industrial interest or that the interest was too short term and piecemeal2. Another problem was that out of date equipment reduced the attractiveness to industry, while many institutions still have over-bureaucratic procedures and uncertain guidelines by which academics can take on paid consultancy and outside work. In some institutions payments are supposed to be negotiated through the department with the individual receiving little direct cash reward, while in others staff are free to sell their time for personal gain. If industrial support is to grow and be seen as an integral part of an academic's timetable and reward structure, in part compensating for a low academic salary, then the institutions will need to be clearer and more positive towards the development and management of such links. And indeed some academics will have to start sharing their additional income with their full-time employers. It will take time for the links to develop as fully and as far as they have in the United States. The ultimate question for the United Kingdom is whether the industrial support will build on government funding or be seen as another reason for further reducing central expenditure on higher education and increasing the reliance or market forces.

Richard Pearson is at the Institute of Manpower Studies, Mantell Building, University of Sussex, Brighton BNI 9RF, UK.

NMR IMAGINO OF A SINGLE CELL

Why buy the fastest gel casting system if you're short on time?

LKB's UltroMould is the fastest way to cast an electrofocusing gel. But if you want more productive results in even less time, you'll stop casting gels altogether.

There's a new alternative. A dried gel with an immobilized pH gradient. The Immobiline DryPlate." You'll get very high resolution and sample load. Put an end to drift, conductivity gaps and batch variations. The Immobiline DryPlate offers you today's most advanced electrofocusing opportunities. With runs that give you more information, a technique with outstanding flexibility and a system that provides unrivalled value for money. Time and again.

Our new brochure tells you why. It also contains the unique User Electrofocusing Guide – an invaluable aid to improving your results. Naturally if you've got the time, we'll be happy to show you UltroMould casting gels faster than you ever thought possible. But if you're truly short on time, just get a copy of "Immobiline DryPlate" – for modern electrofocusing.

Immobiline is a registered trademark of LKB-Produkter AB.

nature

NATURE VOL. 322 10 JULY 1986

A nuclear magnetic resonance (NMR) image of a single Xenopus laevis ovum. The new technique of NMR imaging microscopy, described on page 190 and discussed in News and Views, can be performed on intact living systems with no sectioning, fixing or staining. The cell nucleus is clearly visible (light blue) and the cytoplasm displays heterogeneity. NMR provides information on the state of the water in cytoplasm and nucleus and chemical-shift imaging then gives an indication of the chemical composition of the cytoplasm.

-GUIDE TO AUTHORS

Authors should be aware of the diversity of Nature's renderships and should strive to be as widely understood as possible.

Review articles should be accessible to the while readenship.

Most are commissioned, but unsoluted reviews are welcome
(in which case prior consultation with the office is desirable).

Scientific articles are research reports whose conclusions are of general interest or which represent substantial advenges of understanding. The fext should not exceed 3.000 words and six displayed from (figures plus tables). The article should include an italic heading of about 50 words.

Letters to Nature are ordinarily 1.000 words long with no more than four displayed items. The first paragraph (not exceeding 150 words) should say what the letter is about, why the study it reports was undertaken and what the conclusions are

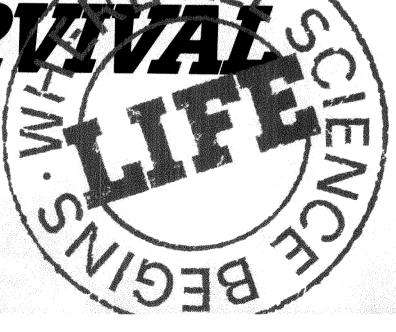

Matters arising are brief comments tup to 5000 words (on articles) and letters recently published in Nature. The originator of a Matters Arising contribution should initially send by mainscript to the author of the original paper and both parases should, wherever possible, agree on what is no be submitted.

Manuscripts may be submitted either to London or Washington, Manuscripts should be typed (double specing) or one side of the paper only. Four copies are required, each accompanied by copies of lettered artwork. No title should exceed Wichardeter in length. Reference lists, figure legends, etc., should be asparate sheets, all of which should be manuscred. Addressing tions, symbols, units, etc. should be identified on one edge of the manuscript at their lists appearance.

References should appear sequentially indicated by superscripts, in the test and should be abbreviated according to the World List of Scientific Periodiculs, fourth edition (Butterworth 1963-65). The first and last page numbers of each refrequenshould be etted. Reference to books should clearly indicates the publisher and the date and place of publication. Unpublished articles should not be formally referred to unless accepted or submitted for publication, but may be mentioned in the text.

Each piece of artwork should be clearly marked with the author's name and the figure number. Original artwork should be unlettered, Suggestions for cover illustrations are welcome. Original artwork tand one copy of the manufectiff will be returned when manuscripts cannot be published.

NATURE VOL. 322 to JULY 1986

Europe in trouble over aviation

Europe's failure to make a common market of itself is typified by the continuing muddle over civil air transport policy. The time has come to change that.

Fig. European Community is miscalled the "common market". So much is clear from the evidence that repeatedly comes to light of how its tolerance of restraints on free trade are crippling for the economy of Europe (see, for example, *Nature* 322, 2; 1986). But most of the time, the scale of this self-inflicted damage is hard to assess. Even the brashest of economists would be at a loss to tell what price Europe pays for its decision to forgo the benefits of a sensible division of labour among competing companies in fields such as electronics or general manufacturing. But in air transport the disbenefits are conspicuous.

Most European governments maintain civil airlines ostensibly as a means of enabling private persons to move from one place to another, but then come to regard them as extensions of the national persona, along with their national anthems and national flags. Europeans pay for these conceits in two ways: by extra taxes which allow governments to subsidize national airlines, and then by the higher fares which also partly compensate for inefficiency. It is especially scandalous that the European Commission should for so long have tolerated a state of affairs that cramps what should be one of the essential elements of the Europe it seeks, people's freedom to move about. It is similarly outrageous that the benefits of a now-traditional technology should be so widely withheld from 300 million people.

Now, luckily, some governments are becoming restive, with the Commission showing signs of waking up to its responsibilities. Motives are, inevitably mixed. The British government, which has been pressing for reform for the best part of three years, is eager that its own nationalized airline, which has been forced by the deprivations of recent years to become efficient and which is about to be sold as a going concern, should be able to compete more freely for the untapped market in European air travel. It would also be a legislative convenience if the government, when "privatizing" British Airways, were able to dispense with the usual monopolies by saying that competition is free. (There are at least two other privately held British airlines that could compete more effectively if allowed.) The Netherlands government is in a similar condition, eager that aviation should become a business rather than a branch of government.

The crucial step that may eventually unlock the jam is that the European Court has ruled that the Treaty of Rome, which created the "common market" in the first place, applies to aviation as to other kinds of business. At last, the Commission seems to have woken up. There is now talk that it will be writing to European airlines, possibly this week, with a warning that they must stop price-rigging and their other restrictive practices. The snag is that the Commission's only sanction is to take offending companies to the courts, not a speedy remedy. That is why hopes still centre on the prospect of a deal between the governments.

But what? The difficulty is that even the most fervent advocates of liberalized European air traffic seem to shrink from outright deregulation. Even the visionaries suppose that air traffic within the ten member states of the Community will continue to be regulated by a series of bilateral agreements between governments, so that aircraft bound from, say. Rome to London calling at Paris will not be free to pick up extra passengers on the second leg of their flight unless that right has been separately negotiated. Instead, the hopefuls model their ambitions on the present agreements between the British government and those of The Netherlands and Belgium, which allow all airlines to fly between designated point at the frequencies they choose, and with whatever fares they fix, provided that both governments choose not to object. These arrangements are better than nothing, but fall short of what they might be. What Europe needs, in this connection as in others, is true competition. In particular, it should be understood that subsidizing airlines is as illegal as subsidizing, say, motor manufacturers (for, otherwise, wasteful carriers will be perpetuated), that airlines of any European nationality may fly between any pair of cities already connected by scheduled services and that there should be no restraint on the ownership, within Europe, of privately held airline companies. That is what the airline business will have to come to in the end. The European Commission should face up to that now, not later. Until it does, the benefits of a simple technology will remain in escrow.

Broadcasting by numbers

Another British government has failed again to find a way of living without the BBC.

If we have enemies like that, what need have we of friends? That must be the reaction of the British Broadcasting Corporation (BBC) to last week's report of the committee under Professor Alan Peacock set up just over a year ago to find politically more palatable ways of supporting British public broadcasting, which is at present done by requiring those who use television receivers to buy an annual licence to make the practice legitimate. The Peacock committee came into being to spare the present government and its successors (of all parties) the periodic problem of deciding how much the licence fee should be, which is politically as popular as deciding by what degree politicians' salaries should be increased. The present government's suspicion (conviction?) a year ago was that advertising was the answer.

Expectations have not been realized. Peacock says that there is not enough advertising to sustain both public service broadcasting and the commercial stations. That is why the BBC is temporarily relieved. But then the committee goes off in a quite unexpected and technological direction, saying that the problem of financing the BBC independently of government decisions about a licence fee will be solved in the distant future, when it becomes possible to ensure that people pay each time they watch a television programme put out by the public broadcasting network. To the Peacock committee, it seems a minor matter that the technology for bringing this about, easily designed on the back of an envelope, is still far beyone most manufacturers' ken. It is nevertheless odd that a committee apparently willing to accept its marching orders, to devise alternative financing. should have sought refuge in technological futurology from the awkward truth that free-market remedies in present circumstances would kill standards. It would have been better to say outright that the BBC, for all its many faults, is probably worth keeping the way it is.

Space vehicles

British HOTOL closes in on French Hermes

BRITAIN'S horizontal take-off and landing space plane, HOTOL, could be in space by 1998, according to the director of the British National Space Centre (BNSC). Roy Gibson. A bid to make it a European project will be made at the next (October) council meeting of the European Space Agency (ESA). HOTOL, which was little more than a gleam in a British Aerospace designer's eye a couple of years ago, thus seems to be racing ahead. With its launch date brought forward, what once seemed almost science fiction is now in direct conflict with the more conventional French project Hermes, in which a mini-shuttle could be launched on top of a cryogenic Ariane-5 rocket around 1995.

But will HOTOL work? According to British Aerospace, the design incorporates a "breakthrough" in air-breathing engine technology which makes it possible to move ahead with off-the-shelf technology rather than the completely new engineering needed for the US National Aeronautics and Space Administration's "National Aerospace plane" (NASP) programme. The NASP programme is aimed at pushing ahead with research in high temperature materials and computational hypersonic fluid dynamics to enable, early next century, the creation of a whole class of vehicles from long-range airliners to spacecraft capable of airbreathing propulsion at speeds of Mach 5-12. By comparison with HOTOL, NASP is "technology driven" according to the British Aerospace Launch Vehicles Project Manager, Bob Parkinson. "HOTOL is a conceptual, not a technological breakthrough", Parkinson claims.

According to Parkinson, "we saw a way of doing the propulsion system that noone else has spotted.... We took the engine concept to Rolls-Royce" and HOTOL began to roll. That was a couple of years ago. But the "breakthrough" is still classified. Commentators have suggested the engine might precool inlet air with its liquid hydrogen fuel, to increase the density of the air and allow the production of a more compact engine. A Rolls-Royce spokesman said that the same engine, once the vehicle reached Mach 5, would be switched to liquid oxygen oxidant to complete the push into

Professor J.E. Ffowcs Williams, of the Department of Engineering at the University of Cambridge, many of whose staff work on Rolls-Royce contracts, said that though he knew little about the project he believed it would benefit from publicity at

this stage. Arthur C. Clarke, the science fiction writer, said from Colombo last week that he invented the idea of the airbreathing engine for space vehicles "40 years ago". But Clarke could not speculate on the British Aerospace design because "I don't know anything about engines and aerodynamics".

Meanwhile, Gibson and others backing the British space effort have the task of raising money from abroad for what is estimated as a \$4,500-million project to produce two flying HOTOL vehicles by 1998, without the freedom to expose the HOTOL "breakthrough". Nevertheless, says Gibson, BNSC has made "progress" in getting HOTOL declassified, as the classification was much more commerical than military. "We've been able to lift the veil enough to make a tour round Europe", seeking participants.

According to Gibson there remain a few technological "hoops", but all should be clear a year or so from now. The British plane is to present ESA members in October with a proposal for a four-year, \$400-million HOTOL feasibility study; but this will clash, politically at least, with the simultaneous effort being made by the French to win participants in a cheaper. \$48-million study of their Hermes space shuttle. Hermes is ahead on the political timetable, as ESA passed an "enabling resolution" approving the study in June (only the money is yet to be found); and it is also ahead on the engineering timetable (as the French space agency CNES has been working on Hermes far longer than the British on HOTOL). But Germany has been hesitating to give full support to Hermes, and according to a Bonn research ministry spokesman, HOTOL has already won the heart of his minister. Heinz Reisenhuber.

France has said it will go it alone with Hermes if it cannot raise European support. Britain, however, is sounding equally bullish about HOTOL. According to Gibson, whose first British space plan will go to ministers this week, participation of the French in the HOTOL programme would not be essential.

There is no French technology that can ot be found or developed elsewhere, ac ording to Gibson, and even French money may not be essential. It is not inconceivable, therefore, that HOTOL will go ahead like Concorde, the Anglo-French supersonic airliner, as a bi-national project, though this time the nations involved may be Britain and West Germany.

Robert Walgate

Indian science

Making the numbers count

Bangalore

TITE gulf between the industrialized nations of both East and West and developing countries such as India is dramatically illustrated in the latest batch of statistics from the Indian Department of Science and Technology. In one year, India's spending on research and development amounts to just US\$1.52 per head of population, compared to \$361.22 in Switzerland, the country at the top of the league. The United States spends \$303.9. Sweden \$242.26 and Japan US\$231.1. With India at the lower end of the scale are the Philippines (\$1.65) and Pakistan (\$0.49).

The pattern is similar when research spending is seen as a percentage of gross national product (see table) or when the

Expenditure on research and development as percentage of gross national product (1982)

Sweden	4.9
Hungary	3.3
Czechoslovakia	3.8
United States	2.5
Japan	2.4
West Germany	2.4
India	0.85
Greece	0.2
Pakistan	0.2
Philippines	0.2

science enterprise is assessed in terms of the number of scientists and technologists per head of population. Compared with nearly 140 per thousand of population in the United States, for instance. India boasts a mere 2.63 per thousand. Yet in a country as big as India this means there were 2.47 million scientist and technologists in 1985, up from 1.95 million ion 1980.

It is this two-million-plus science workforce that Prime Minister Mr Rajiv Gandhi sees as the key to India's welfare in the twenty-first century. His new science policy identifies three levels of projects: "missions", where scientists will need to put proven technology to work to solve specific problems: "thrust areas"; and "blue-sky" basic research. The emphasis in each area, is to be on the possible benefits for the "common man", most particularly India's rural population.

Five of the "missions" have already been selected — improving drinking water, campaigning against illiteracy, telecommunications, a vaccination programme for children and in agriculture a major effort to improve oil seeds. The "thrust areas" so far proposed are computer technology and biotechnology — frontier disciplines requiring major investment but with the potential to give immediate results.

Scientific American

Unwanted fly in merger ointment

THE fate of 141-year-old Scientific American, which claims to be the oldest periodical in the United States, hung in the balance earlier this week, after an agreement by the board of Scientific American Inc. to merge with a West German publisher had been confused by a rival bid from Mr Robert Maxwell, the British publisher and owner of Pergamon Press. Mr Maxwell was bidding through the vehicle of the public company, BPPC, in which he holds a controlling interest. It will be for the shareholders in Scientific American Inc., which is not quoted on the stock exchanges, to decide whether to accept the board's proposal or that from Maxwell.

The board's proposal, agreed at a meeting in New York on 30 June, is that the West German company Verlagsgruppe Georg von Holtzbrinck of Stuttgart should be allowed to offer the shareholders of the US company \$258 for each of their shares, amounting to a total of \$52.6 million for the company as a whole.

Holtzbrinck's business centres on the publication of the newspaper Handels-blatt, a financial daily, but the company has been since 1981 a partner in the publication of the German edition of Scientific American (under the title Spektrum) and has recently been expanding into the US publishing industry by the acquisition of book-publishing companies.

Under the proposed arrangement, which includes the sale of the book publisher W.H. Freeman Inc., Scientific American would continue to operate as an independent enterprise, with Mr Gerard Piel continuing as chairman of the management board and his son, Mr Jonathan Piel, as editor and publisher. The younger Piel said last week that Holtzbrinck was enthusiastic about his plans for increasing the coverage of news in the magazine.

The present uncertainty is an ironic outcome of a process extending over the past three months, since the impending sale of Scientific American Inc. was first announced, and during which the New York investment (merchant) banker Salomon Brothers was commissioned by the board to conduct a "regulated auction" of the company. This is a process by means of which potential bidders can be screened so as to exclude unwanted owners. Sealed bids were received on 16 June from seven different organizations, including one from Maxwell of \$34 million.

Even the idea that Scientific American might be put on the block would have seemed strange a short while ago; during the 1960s, the monthly magazine was among the most successful of internationally circulating publications, both commercially and in reputation. In spite of its antiquity, Scientific American's success is

entirely a post-Second-World-War phenomenon deriving from the acquisition of the title by Gerard Piel and Denis Flanagan, the editor until four years ago.

The need to sell the company has largely arisen because of the discontent of some shareholders. The proportion of shares controlled by Gerard Piel is believed to be about one-sixth, not enough to prevent a sale. The largest shareholder, with 32 per cent, is Mr Arthur Seckler, well known for charitable works.

The company's announcement last week of the agreement with Holtzbrinck said that the board had confirmed this arrangement in spite of the receipt of a letter "from the bidder who had originally offered the lowest price... purporting to raise that offer to \$61 million".

Although the company says that it has legal grounds for not recommending Maxwell's bid to its shareholders, there is no obvious reason why the shareholders collectively should not let strictly financial considerations determine their decisions. The next step is, apparently, that Holtzbrinck will make a formal offer to buy the shares. A spokesman in Maxwell's office said this week that it would be for the board of *Scientific American* to consider the BPPC offer in the "light of its fiduciary

responsibilities to shareholders".

The uncertainty has nevertheless caused consternation among authors of W.H. Freeman, who appear to be alarmed at the transfer of ownership to Maxwell. Dr Harvey Lodish of the Massachusetts Institute of Technology says that he will not revise the first edition of his successfully published book if the threatened deal goes ahead. Dr Peter Atkins of the University of Oxford, whose successful textbook Physical Chemistry is published in the United States by W.H. Freeman, says that neither the shareholders nor the purchaser should be in doubt that the sale may be that of a "shell" if Freeman authors choose to defect.

Professor Martin Rees (Institute of Astronomy, University of Cambridge), who is writing a book for Freeman but who has not yet signed a contract, says that he is more offended by statements in a circular letter to BPPC shareholders three months ago explaining the basis which the titles of 361 titles of scientific journals were transferred from Pergamon Press to BPPC in exchange for £240 million. The circular says that, because scientists are more concerned with quality than price. prices of journals can (and have been) increased "well above the rate of inflation". In 1985, the prospectus says, the 361 journals will make a profit "before sales commission" of £23.7 million on a turnover of only £49 million. John Maddox

Others have problems too

POPULAR science magazines have suffered serious falls in advertising revenue recently from which even the relatively serious *Scientific American* has not been excepted. According to the US Publishers' Information Bureau, *Scientific American*'s advertising revenues have fallen by 27 per cent in the past year. The slump in the home computer market is one reason; although corporate advertising partly made up the shortfall, it too fell in the last year. Sales, at around 600,000 copies, are down from a peak of 720,000 in the late 1970s, mainly because of competition from the more popular magazines.

Mr Gerard Piel, chairman of Scientific American Inc., denies, however, that reduced revenues were the immediate cause of the sale; rather, he blames the "extremely turbulent corporate market" of recent years and the "staggering" frequency of mergers which threatened Scientific American with the possibility of a takeover by an unfriendly bidder who would not uphold the magazine's standards.

Falling advertising revenues are. however, blamed for the demise two weeks ago of *Science 86*, the popular publication of the American Association for the Advancement of Science. Time Inc. bought the magazine's assets for \$6 million and turned the subscriber list over to its own popular magazine Discover, which can use the Science 86 logo for 2 years. Discover has, however, been drifting away in recent months from science towards being a general consumer/ current affairs magazine. Science 86's advertising revenues dropped by 50 per cent in two years. Editorial staff are being "terminated".

Why has there been such a precipitous decline in advertising in popular science magazines? Different people have different answers, but the decline of the home computer market — and competition from specialized home computer magazines — is frequently mentioned. Some advertising agencies believe that readers of such magazines are not sufficiently consumerminded, and that similarly affluent readers can be reached to greater effect in consumer magazines, which are also read by more people per copy. Others point to proliferation of popular science magazines in the early 1980s. But many agree that one more magazine will have to go before equilibrium is reached. The most vulnerable, by common consent, is Science Digest. Its advertising revenues fell by 50 per cent in the past year, and even the wealthy Hearst Corporation is unlikely to continue supporting a loser for ever. Tim Beardsley

AIDS

New centres for clinical trials

Washington

As the number of cases of acquired immune deficiency syndrome (AIDS) continues to snowball, finding an effective therapy becomes increasingly urgent. The US National Institute of Allergy and Infectious Diseases (NIAID) announced last week that it was committing \$100 million over the next five years to speed the search for a therapy.

Fourteen AIDS treatment evaluation units will be set up around the United States to test drugs that have shown some promise, either by blocking replication of the virus that causes AIDS, or by strengthening immune system function. Therapies likely to be tested in the first year of trials include the anti-viral compounds azidothymidine, foscarnet, HPA-23, ribavirin, interferon-alpha and possibly dideoxycitidine. In announcing the new units, Anthony Fauci, director of NIAID, said a successful treatment would probably combine an anti-viral drug with an immune modulator. But combination therapies will be tested only after each single agent is tested.

A Data Safety Monitoring Board will evaluate the progress at each centre recommending new directions on initial results. To streamline exchange of information among the 14 units, NIAID plans to award a contract this September for a trial coordinating centre.

While Fauci estimates that some 2,000 patients will be included in trials by the end of the first year of the programme, the centres are not intended for treatment of the nearly 22,000 people with AIDS in the United States. Plans for placebo-controlled clinical trials has renewed the debate over the ethical justification of such an approach. Robert Levine, chairman of the Yale University School of Medicine Institutional Review Board, has suggested that using historical controls may be an "ethically less problematic" research design than placebo controls.

But Walter Dowdle, AIDS coordinator

Centres named

The fourteen institutions receiving NIAID funds are: Harvard University; John Hopkins University; Memorial Sloan-Kettering Cancer Center; New York University; Stanford University; University of California, Los Angeles; University of California, San Diego; University of California, San Francisco; University of Miami; University of Pittsburgh; University of Rochester; University of Southern California; University of Texas M.D. Anderson Hospital and Tumor Institute; and University of Washington.

for the Department of Health and Human Services Public Health Service (PHS), says that controlled trials are the "most compassionate way to go". Dowdle argues that, in the long run, only placebo-controlled trials will show which therapies are truly effective. Dowdle is also sceptical about providing experimental drugs to patients not involved in clinical trials. As no agent has been shown to be safe and effective against the AIDS virus, providing unproven drugs to patients could accelerate the course of their disease.

Critics of the government's response to the AIDS problem say that the present

administration has not gone far enough in dealing with the problem. In an occasionally heated congressional hearing last week chaired by Representative Ted Weiss (Democrat, New York), Martin Hirsch of Harvard University testified that it is "a national tragedy that so few patients" are in controlled clinical trials for AIDS therapies. Dowdle and Fauci defended NIAID's plans, but when questioned, Fauci admitted that additional money would allow NIAID to support another five centres whose applications had received favourable reviews. Weiss was quick to insist that PHS should request the money in its 1987 budget. After the hearing, Dowdle said PHS was considering asking for more cash, but no decision had yet been made. Joseph Palca

OECD report

Sweden number one for research

Sweden "has more to teach than to learn" about research and technology policy, according to a team of distinguished examiners for the Organisation of Economic Cooperation and Development (OECD) whose report on Sweden has just been released*. Swedish industry spends more on research and development per unit of turnover than even Japanese industry, according to the report. Over the past 15 years, Swedish business has raised its receipts from patents sold abroad eightfold—while its payments for foreign technology licences has risen only fourfold.

Despite this success, the examiners complain, Sweden pays university professors only 50 per cent more than it pays university janitors. University posts remain unfilled and there is a danger that the education system will not continue to provide the technically trained manpower that Sweden's established high-technology industry needs. Between 1970 and 1984, the numbers of doctoral graduates in physics, chemistry and mathematics in Sweden fell 50-75 per cent. OECD lays the blame on a system of loans, repayable after graduation, to cover higher education fees. Loans discourage students from entering research careers. A further degree means further debts, and a doctorate does not lead to higher salaries, or at least not sufficiently high to pay off the extra debt.

Yet Sweden depends on science. Its pharmaceutical and biomedical industry spends 17–18 per cent of its turnover on research and development. Including government spending, Swedish spending per head of population on biomedical research is higher than that of the United States, the OECD examiners claim.

Swedish communications engineering, environmental research, energy-saving equipment, paper-making technologies and robotics are equally advanced. The

use of robots in Swedish industry had reached 29.9 per 10,000 workers by 1981—the highest in the world, ahead of Japan (13.9 in the same year) and the United States (4.0).

The examiners congratulate Sweden on its enlightened workforce, and the "generally pro-science and technology attitude" in the country. This might be attributed, they suggest, to a strong programme by the national council for planning and coordination of research (FRN) in the schools, teaching children about energy problems, cancer, food and the like, an effort the examiners describe as "unprecedented in OECD countries with the possible exception of Japan".

The level of expenditure aimed at industrial development is now so high, however, that Sweden is in a class of its own, with no other country to learn from. Sweden is itself now an experiment, which other countries will watch with interest, to see the effects of this strategy.

A constant theme throughout this report from OECD, however, is that Sweden must beware of taking its renowned egalitarianism too far, at least in research. Swedish success in biomedicine, for example, is traced to the Nobel prize winner Theodor Svedborg and his successors at Uppsala; and the chemical industry to Nobel himself and precision instrumentation to Hasselblad. "We recommend that allocation of funds be made to individuals of excellence, with far-reaching plans, not to fields... and that high quality results be recognized by easy and substantial funding." **Robert Walgate**

*OECD Reviews of National Science and Technology Policies: Sweden (OECD Paris. 1986). The review panel consisted of: Guy Ourisson, director. Institut de Chimie des Substances Naturelles, Gif sur Yvette, France: Walter Zegveld, director, Policy Studies and Information Group, TNO, Delft, The Netherlands; Derek Denton, director, Howard Florey Institute, of Medicine. University of Melbourne, Australia: and Yrjo Toivola, managing director, Vaisala Oy, Helsinki, Finland.

Launch vehicles

France and US explain failures

AFTER third-stage ignition failures which destroyed two of the last three launches, the European space rocket Ariane looks set to go back to the makers for six months. The independent commission of inquiry which reported in Paris last week attributed Ariane's latest problems, and uncertain ignitions and failures early in the programme, to the small size of the "pyrotechnic" that lights the engine.

This view appears to counter speculation in the Los Angeles Times earlier this week that senior French sources believed Ariane had been sabotaged, but Jacqueline Schenkel of the Arianespace Washington office would say this week only that sabotage "had been practically ruled out". Certain questions are in fact "still being investigated" she said.

Ariane's third-stage, liquid hydrogenoxygen engine is ignited by a four-second pyrotechnic burning in the combustion chamber. But sometimes the fuel has failed to ignite; at others it has back-fired and gone out or faltered but continued. Ignition has proved to be sensitive to too many factors. The tolerances of the process have to be broadened, the commissioin says, and the easy solution is a bigger pyrotechnic.

This will take approximately six months, but in the face of similar launch difficulties in the United States with the shuttle and conventional rockets, Arianespace is still enjoying a burgeoning order book. Orders for 36 satellites to be placed in orbit at a net cost of some £1,000 million are still in hand, the company says.

Meanwhile, in Washington, explanations for US rocket failures abounded last week. At the Pentagon, the Air Force explained why its Titan 34D booster exploded seconds after lift-off. Over at the National Aeronautics and Space Administration (NASA), an investigation revealed faulty wiring as the cause of the failure of a Delta rocket on 3 May. Neither investigation showed fundamental flaws in rocket design, and launches could resume as soon as new prelaunch procedures can be implemented.

The Titan's problems started when rubber insulation apparently pulled away from the steel wall of the solid rocket motor (SRM) shortly after lift-off. This allowed combustion products to reach the booster wall, weakening it to the extent that it could no longer withstand the pressures inside the booster. Approximately 9 seconds after SRM ignition, the rocket exploded, causing \$70 million damage to the launch pad and adjacent facilities.

The Titan 34D SRMs are similar in design to those used on the space shuttle, but have a different manufacturer — United Technologies rather than Morton Thio-

kol. The commission investigating last January's shuttle disaster concluded that a failute of the O-ring seals caused the Challenger accident. But General Nathan Lindsay, who headed the Air Force investigation, said the O-ring seals joining the solid rocket segments "did not contribute to the [Titan 34D] mishap".

Lindsay does not believe that the accident represents a flaw in the SRM design. He pointed out that 940 booster segments have launched successfully without a problem. The Air Force plans to upgrade its inspection procedures of the solid rocket motor segments, but otherwise is

making no major alterations in the Titan 34D as a result of the accident. Lindsay expects that Titan 34D flights will resume within a year.

The problems of the Delta rocket were primarily electrical, according to NASA's investigation. A short in the main engine control circuits caused both the main and altitude engines to shut down. Without controlling thrust from the engines, the Delta broke apart in the atmosphere and was destroyed by ground controllers. Vibration at lift-off apparently caused the erosion of some insulation in a wiring harness, leading to the short circuit. NASA's investigation board recommended redesign of parts of a wiring harness, as well as increased attention to detail in construc-Robert Walgate & Joseph Palca tion.

Nature conservation

Too many of the wrong trees?

In a country as stripped bare of woodland as Britain, it might seem certain that the planting of new forests would be universally welcomed. But last week, all the nation's major voluntary conservation bodies

joined hands in a report protesting against the rapid growth of Britain's forests.

The report comes from Wildlife Link, which represents 24 conservation organizations with a total membership of 1.4 million. It is not more trees that they find objectionable but that present government policy, grants and tax relief favour a type of forest practice which they believe is damaging to the environment. The pace of planting has certainly increased: nearly 5.5 million acres of new forest a year, double that of fifty years ago. And, says the report, much of that is in massive monocultures, usually of Sitka spruce, that are transforming open land habitats and destroying the flora and fauna of moorland, heath, bog and sand dune. Two and a half million acres have gone since 1919. Vast areas of Scotland are now "tree farms" which destroy wildlife and are utterly different from any native forest that might once have grown there.

The critique by the conservation organizations comes a week after the publication by the Nature Conservancy Council of Nature conservation and afforestation in Britain, which details the increasing conflict between forestry interests and conservation needs. Each of the arguments for further massive plantations - that there is still plenty of open land left; that, as much of what is now open land was once forest, afforestation is a return to a more natural environment; and that forests support more wildlife than open ground - is examined and found wanting. Nor does the report find economic arguments compelling. Although Britain imports 90 per cent of its timber so that the need for increased domestic production would seem vital, forestry gives a low return on capital invested and takes up funds that might be better spent elsewhere.

The conservation bodies would like to see more sensitive planting, particularly using native tree species, in a manner that would help to increase the diversity of wildlife and avoid damage to unique open habitats. Various possible new planning control methods are suggested, but the first task remains to notify all Sites of Special Scientific Interest (SSSI) and to ensure that they are adequately protected. One possibility might be a stronger regulatory role for the Forestry Commission which processes applications for forestry grants. But the commission would first have to strike a better balance between timber production and protection of the environment in its own activities.

In the longer run, new and more attractive forestry schemes may appear. There is pressure within the European Community to reduce excess food production by converting relatively fertile farmland to forests. These lowland forests could be of native hardwoods and support rich wildlife communities; quite different from the massive forests being grown on the northwestern moorlands.

National Science Foundation

Grant applications go paperless

Washington

EXPRES, the National Science Foundation (NSF)'s plan to make grant application all electronic, will take off at the end of this month. NSF hopes the project will streamline its review process and serve as a prototype for the exchange of scientific information between different computer environments. But success depends largely on factors outside NSF's control.

Formally titled Experimental Research in Electronic Submission, EXPRES

Eucalyptus clean-up

New Delhi

India's northern state of Haryana appears to have found one solution for a major problem of developing countries — how to dispose of sewage cheaply. A five-year project at the Central Soil and Salinity Research Institute (CSSRI) at Karnal has revealed that untreated sewage is just the thing to encourage eucalyptus forests to grow on wasteland.

When the CSSRI scientists began their project back in 1981, they simply pumped sewage into trenches on wasteland and planted eucalyptus trees on ridges between them. Now the wastelands have turned into eucalyptus forests, previously used sewage ponds have disappeared and there a fewer mosquitoes.

"Land disposal of sewage is the cheapest and most cost-effective method of disposing of urban waste waters as it utilizes the entire biosystem - soil and vegetation as a living filter", says Dr Ranbir Chabbra, a senior soil scientist at CSSRI. Untreated sewage contains large quantities of plant nutrients but the presence of pathogens, heavy metals, pesticides and above all its odour makes it unsuitable for growing agricultural crops and vegetables. But these considerations do not affect its use for growing trees which are used as timber and fuel but not as food, says Chabbra. As the trees act as biopumps, they prevent water-logging and thus groundwater pollution.

There are two reasons why the eucalyptus system is particularly attractive to the Haryana towns. First, CSSRI has shown that one hectare of eucalyptus irrigated by sewage water can earn the municipalities a gross return of Rs 9,700 (£600) in the first year and Rs 28,000 (£1,800) in the second year. The sludge accumulating in the furrows, which can be sold as manure, is a bonus. Second, the technology raises the prospects of developing plantations into green belts and scenic parks. No wonder the project has the approval of the state forest department as well as the pollution control board. K.S. Jayaraman would shift proposal development, submission and review from reams of paper to the realm of computer workstations, so that a proposal could be distributed from its origin to NSF, and from NSF to reviewers, entirely by electronic transmission. Because the grant-seeking community is both technologically and geographically diverse, NSF thinks the scheme makes the perfect guinea pig for research on information exchange. The foundation receives ten copies each of 37,000 proposals from about 2,400 organizations in an average year.

The inspiration for EXPRES came from the NSF office that processes grant proposals, and gained impetus when Erich Bloch, a former vice-president at IBM, became NSF director in 1984. The foundation expects to announce two award recipients in September, and has earmarked \$2 million for EXPRES in fiscal year 1987.

Although the duration of the awards is three years, funding for the remaining two is not "set in concrete". Competition for the awards may be keen nonetheless: an interest meeting last month drew more than 30 people, and nearly 200 organizations have requested project solicitations.

Part of the reason that EXPRES has sparked this response has to do with its applicability beyond the paper-shuffling procedure at NSF; as project manager Alvin Thaler claims, "the grant process is just a handle to grab hold of the whole problem of communicating scientific information". Ultimately, however, the project's implementation depends upon concurrent developments in computer standardization to lay the groundwork for open information exchange. EXPRES pilot installations will intially use NSFNET, a network that links the foundation's supercomputers and is itself still in its formative years. Although NSFNET currently conforms to DARPA protocol (a system developed by the Department of Defense), it will eventually adopt the universal Open Systems Interconnection (OSI) standards of the International Standards Organization. But OSI standards are also in their infancy, putting another question mark in the EXPRES timetable.

The birth of EXPRES, therefore, needs to be closely attended by the groups responsible for computer standards, such as the National Bureau of Standards and the American National Standards Institute.

The project may also have an ally in the Virginia-based Corporation for Open Systems (COS), an organization conceived just last year to accelerate implementation of OSI by coordinating industry efforts towards standardization. With 55 members, including IBM, AT&T and Digital Equipment Corporation, COS could

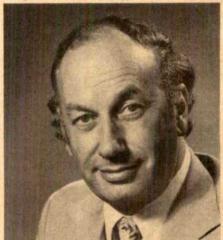

hasten the industry-wide compliance that NSF needs to make EXPRES operable. The view from COS is clear: programme manager Vance Mall says that if all concerned parties pool their efforts, EXPRES could be up and running by 1990.

Karen Wright

Vane back to basics

WITH the financial backing of Glaxo, the British pharmaceutical company, Sir John Vane is going back to his pharmacological roots, a year after leaving the Wellcome Foundation, of which he was research director.

Vane will direct the new William Harvey Research Institute at St Bartholomew's Hospital Medical College, situated close to

St Bartholomew's Hospital, where William Harvey established that blood circulates, but even closer to Smithfield, London's central meat market. Funds will be available for about a dozen scientists plus support staff for at least five years to carry out research on cardiovascular disease, with particular emphasis on atherosclerosis and eicosanoids, the area of research for which Sir John shared the 1982 Nobel prize for Physiology or Medicine.

The first of Vane's priorities is to stock the institute with Watenabe rabbits or other animal models of human atherosclerosis. With these and with the aid of cell culture and his own cascade bioassay system, Vane intends to improve the understanding of the pharmacology of cardiovascular disease. Against the trend, he has no plan to use the techniques of molecular genetics in the institute's research.

In return for financing the new institute, Glaxo has first rights on any discovery of commercial interest to it. Sir John is the second top Wellcome researcher to be snapped up by Glaxo; earlier this year, Dr Pedro Cuatrecasas left his position as head of research at Burroughs Wellcome, the US subsidiary of Wellcome plc, to set up a US research operation for Glaxo Ltd.

Peter Newmark

Animal welfare

Laboratory animals unprotected

Tokyo

DEBATE over the welfare of laboratory animals in Japan has been sparked by reports from a French scientist that monkeys at Kyoto University's Inuyama Primate Research Institute have been shamefully maltreated. Bernadette Brésard, who carried out research at the institute last year, has revealed to French magazines that monkeys were routinely restrained in "monkey chairs" for months on end. Behind this one incident lies a much deeper problem: the lack of clear, enforceable regulations on the treatment of laboratory animals in Japan.

Brésard came to Japan last year with an

Eiffel in orbit

FRENCH engineers, clearly inspired by the recent refurbishment and laser-lighting of the French-built Statue of Liberty in New York, are now planning to put an Eiffel Tower in space.

The object of a competition, announced last month by the Eiffel Tower Company (Société Nouvelle d'Exploitation de la Tour Eiffel), is to design a structure for the space age "as audacious and imaginative as that of Gustave Eiffel for the age of steam". Designs must be for a durable structure visible to the naked eye and symbolizing

"universal communication, the great dream of our times". Otherwise, the structure is to be useless: it must have "no commercial or military function", but "peaceful" and "scientific" uses can be considered. The three best projects will be selected by a jury of scientist, space engineers and artists this October, for prizes of up to \$20,000. There will also be a junior category for under-15s. Actual construction of the winners' projects, however, is not guaranteed.... Further information may be obtained from: La Tour Eiffel de l'Espace, Champ de Mars, 75007 Paris, France.

orang utan, Dou-dou, and a chimpanzee, Chloé, which were exchanged for Japanese macaques from Inuyama. The Inuyama centre, funded by the Ministry of Education, Science and Culture (MESC), was set up as the nations's key primate research centre. But after being recruited by MESC to continue her research on cognitive ethology Brésard soon found herself embroiled in an arguement.

The monkeys were confined day and night for several months in makeshift chairs with a stock-like clamper device around their necks so that electrical recordings could easily be taken from their brains. The monkeys' necks became ulcerated and their testicles degenerated because of the prolonged immobilization.

Horrified by the monkeys' condition, Brésard requested their immediate release, but she was told by members of the psychology department to which she belonged that they had "no right to ask the researchers to release their monkeys as long as they considered it essential for their experiments". Instead, Brésard was nominated to join an informal working group on animal welfare set up by associate professor Toshio Asano of the psychology department who also chaired the institute's ad hoc animal welfare committee. But, frustrated by the working group's prolonged deliberations, Brésard turned to the French magazines, Geo and La vie des bêtes.

No sooner did the articles appear than the Japanese embassies in France and Switzerland were inundated with complaints and the Foreign Ministry asked MESC to investigate. But the Inuyama researchers pointed out that they had been acting within Japanese law and government guidelines.

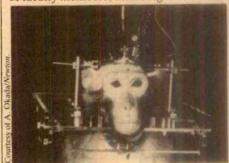

Whereas Western nations have been tightening up guidelines and introducing new laws, Japan still has regulations that are full of loopholes and leave interpretation largely to the "common sense" of the researcher. For example, in Article 5 of the guidelines issued by the Prime Minister's office in 1980, researchers are told to "minimize the pain and suffering of laboratory animals by, for example, giving anesthetics", "provided this does not interfere with the purpose of the experiment".

The regulations have no teeth. There is no system of licensing or government inspection to check that researchers follow the guidelines, no process of review of research proposals, and no requirement to report the number or type of animals used or the experiments carried out. Hence the fine of up to 30,000 yen (£120) for cruel treatment has little chance of being levied.

There are no vociferous anti-vivisectionist groups in Japan campaigning for

animal rights, as there are in the West. The Japan Animal Welfare Society is a moderate group that seeks to reduce experimentation on animals and to alleviate their suffering.

Recognizing that Japan lags behind in animal welfare, the Inuyama ad hoc committee headed by Asano drew up guidelines for the care and use of laboratory primates based on the US National Institutes of Health 1985 guide. Published in April shortly after Brésard left, the Inuyama guide is backed up by an institutional monitoring committee composed of faculty members, including at least one

who is involved in animal experiments; one who is not; and a veterinarian.

With implementation of the guide, conditions for the restrained monkeys have been considerably improved at Inuvama, says Asano. Chairing beyond 24 hours is no longer permitted without consent from the monkey committee, and no requests for chairing beyond 24 hours. have so far been made. When the monkeys are not being used for experiments. attempts are made to bring them together in social groups. Minimum cage sizes are defined and, although cages at Inuvama do not all come up to standard, Asano says they will soon get the 300 cages they require, despite a price of about 150,000 yen (£600) per cage.

The Inuyama guide is now attracting attention. At the annual convention of the Primate Society of Japan in Nagoya in mid-June, members were urged to draw up their own guidelines following that of Inuyama. But the Inuyama guide avoids discussion of an issue that has dominated debate in the West; pain in laboratory animals.

A symposium on this topic was held in Tokyo at the end of May by the Laboratory Animal Society of Japan, but the participants tied themselves up in semantic knots and no significant progress was made.

Although changes have now been made at Inuyama, other institutes are under no obligation to adopt new guidelines. Nor is there any way of checking up what conditions are like in private industry, where there is no requirement to report experiments. Changes in legislation are not at present being considered by the government, but there may be changes in attitude if concerned groups continue to grow in strength.

David Swinbanks

US nutritional research

Your grant is what you eat

Washington

NUTRITIONISTS find themselves divided on the activities of United Sciences of America (USA) Inc. Founded just six months ago, USA intends to put some \$1.2 million a year into nutritional research; the trouble is that the company's profits come from "network marketing" of "revolutionary dietary supplements". Despite USA's distinguished scientific board, many experts are sceptical about the value of dietary supplements for the general population and object to USA's advertising.

USA was founded last year by Robert M. Adler, a telecommunications entrepreneur. Its promotional videos make much of the claimed scientific merit of USA's preparations; a slickly produced 1985 video features views of huge computer rooms where research data is stored, and brief shots of the covers of Nature and the New England Journal of Medicine. The scientific advisory board includes two Nobel prizewinners and other well-known medical researchers. Critics allege, however, that not enough is known about some of the ingredients to recommend dietary supplements.

In addition to a retainer (at least for some members), members of the scientific advisory board get first shot at USA's research awards. Two weeks ago, at a meeting at its Dallas headquarters, USA approved its first twelve awards totalling \$600,000, of which several went to board members. But the meeting also spawned disagreement among the advisory board on the company's use of members' names for endorsements. One member, Dr Alexander Leaf of Harvard Medical College, threatened to resign unless his name was removed from endorsements.

According to Dr Jeffrey Fisher, USA vice-president for product development, the company will eventually offer a nutritional plan, a weight management plan and an aerobic fitness plan. The catchword is "optimal health". So far only the nutritional plan is on the market: it consists of a preparation of vitamins, trace elements and amino acids billed as rich in anti-oxidants; a "fibre energy bar" that includes a complex mixture of carbohydrates and a proprietary blend of cotton seed and surimi protein; a calorie control formula, again with special proteins; and a marine lipid concentrate containing omega-3 fatty acids, antioxidants and garlic extract.

Many of the ingredients are the subject of legitimate research. But many nutritionists question the strength of the evidence on which USA's products are based. Some, such as Dr Robert Good of the University of Southern Florida, chairman of the scientific advisory board, be-

lieve that indirect evidence is sufficient to recommend that the public take, for example, fish oils. But others, such as Henry Kamin of Duke University, who recently chaired a controversial National Research Council dietary study, believe that to offer fish oil supplements to the general public is "grossly premature".

Kamin — and many others — believes that epidemiological evidence (such as the low rate of heart disease among eskimos who eat a lot of fish) should not be used as a basis to "stuff people with fish oils" until possible hazards of long-term use are evaluated. Even if they could benefit some individuals, nobody has any idea of what would be a good dosage of omega fatty acids, according to Kamin. One of USA's recent research awards was to Leaf to investigate the effects of different levels of fish-oil supplements on blood chemistry.

Kamin also argues that there is no need for special protein blends with good amino-acid balance when the typical US citizen daily eats more than three times the amount necessary. He questions the relevance of the scientific advisory board's expertise; although a celebrity cast, few if any members are primarily nutritionists, a point admitted by Fisher.

Other features of the USA products are also contentious. Victor Herbert of Mount Sinai School of Medicine says there is "no evidence" that taking supplementary doses of vitamins E and C above national recommended daily allowances has any protective effect against cancer, a conclusion reached by the National Academy of Sciences in 1982.

USA's advertising is careful not to make any claims about specific health benefits, which would in the eyes of the Food and Drug Administration make the product a drug needing trials for safety and efficacy. But the 1985 video, which dwells darkly on environmental pollution and blames it for high heart disease and cancer rates, manages to suggest directly that USA's products might counter these hazards.

Leaf, chairman of the department of preventative medicine and clinical epidemiology at Harvard Medical College and a member of the scientific advisory board, is quoted in USA promotional materials as saying that "the four formulas of USA Inc. together constitute a nutritional plan that is the finest and most complete I have ever seen". But Leaf denies making such a statement and says he thought he had been "a little naive" in his dealings with USA Inc., having been told only that he would serve as a consultant. Leaf said he was threatening to resign from the advisory board unless his name was removed from product endorsements and that other members had made similar protests. The American Heart Association's logo is also apparently used in the video without permission.

USA's sales method is a source of concern to some. Described by Fisher as "as innovative as the programs", it involves individuals becoming "associates" of the company and then recruiting more associates — similar to "pyramid selling". The Food and Drug Administration points out that it is difficult to police claims made for products sold in private. But Dr Robert Morin of the University of California at Los Angeles, another member of the advisory board, contends that the instructional materials provided by USA Inc. make "network selling" preferable to simple counter sales.

Good says the dietary programme has been established "within conventional scientific wisdom" to provide "undernutrition without malnutrition". Good admitted that he had not seen USA's promotional video. But he is a believer in the benefits of anti-oxidants, which may inhibit some ageing processes. Good says he has been able to forestall death of genetically short-lived animals in all species so far studied, and believes there are sufficient data to promulgate cautiously dietary supplements to the public. And Good believes that a weight-reduction plan must include protein supplements.

Fisher admits that early videos were "too hypish" and says later versions were toned down. And he admits that there is debate about some nutrients in USA products but says science is coming around to USA's point of view.

Tim Beardsley

Young Hungarian

SZEGED University's Department of Natural Sciences has called on the Hungarian government to cut military spending and uneconomic large-scale projects and to devote the money saved to improving higher education and the standard of living of young graduates. Although such issues have been raised before in Hungary's underground press, this is the first time that they have been explicitly stated in an official context, at least since the discussions that led up to the 1956 uprising.

The Szeged group, which consists of young academic and graduating students, submitted its proposals to the Congress of the Hungarian young communist movement in May. Officially they were ignored and, according to some unconfirmed reports, copies of the university newspaper, Szegedi Egyetem, which carried the proposals, have been impounded.

Even apart from the proposal that military spending should be "rationalized", the Szeged document is bound to be controversial. One proposal is that the univer-

Information technology

Where next for Alvey?

Britain's Alvey programme, aimed at strengthening the information technology industries through collaborative research with the universities, appears to be at a critical stage. Last week's Alvey conference made clear that the programme, now halfway through its five-year life, has produced enough successes to excite government, universities and industry. But nobody is sure how to keep the momentum going to ensure long-term industrial success.

The 600 delegates at the conference at the University of Sussex were clearly optimistic about the future. The Alvey programme is a unique attempt to break down the barriers between the universities and industry in key areas of information technology: very-large-scale integrated circuits, software engineering; intelligent knowledge-based systems; and man/ machine interfaces. To ensure industrial involvement, even the smaller basic research projects carried out at universities must have an industrial "uncle" - someone from industry who will alert colleagues when an idea begins to look worth industrial development.

Three hundred and three projects are now under way at a cost of almost £200 million to the government plus a somewhat smaller amount from industry. One hundred and eight companies are participating alongside 53 universities and polytechnics (Imperial College, Edinburgh and Cambridge form the first league), a

academics protest

sities be given real, not merely symbolic, control over their budgets and the right to choose their own officials, rather than have them appointed by the state.

A further suggestion is that student grants should be pegged to keep pace with inflation and that less weight should go to means testing of family income. This would favour better-off families and is liable to be opposed by Party hard-liners.

Another proposal raises the whole question of the relationship between workers and intellectuals in a socialist state. In Hungary, entitlements to annual leave, pension rights and priority for housing are all related to length of service at a particular enterprise. Young graduates entering the system thus find themselves disadvantaged because they are five years behind in acquiring benefits compared with a worker who entered employment direct from school. The Szeged group is now asking for the years of study to be counted in the employment record — a seemingly modest proposal but one with clear political overtones. Vera Rich level of cooperation that Minister of State for Information Technology Geoffrey Pattie described as "probably unprecedented in peacetime". But as John Alvey, who originally proposed the programme, put it, "we have won some victories, but haven't won the war". The test will be the international marketplace. If saleable products cannot be produced, then Britain's industrial position will fall back still further.

Much discussion centred on what must be done to prevent this happening. Those actively involved in research tended to concentrate on the details: is there not, for example, an easier way to cope with drawing up cooperative agreements? Big delavs have been caused. And would it not be wiser to have a central research institute instead of distributing work throughout the participating laboratories? Advantages of the former are that it quickly creates a critical mass of expertise and avoids duplication. But it can too easily become an ivory tower. The really big questions, spelled out by Pattie, were of government support and the balance between national and international programmes. Although everyone would like funding to continue, the pre-competitive research of Alvey must be commercially exploited and the postgraduates who have been trained persuaded to move on to industry.

For the balance between international and national funding, critical decisions must be made soon. The huge industrial high-technology programmes, ESPRIT and RACE (for information and communication technology), lie within the European "research and development framework programme", designed to shape policy for the next five years. The outline of the programme is now before the European Community's science ministers. Where will the post-Alvey programme fit? According to Pattie, international programmes cannot substitute for national ones, for the latter are necessary to give strength in collaborative projects.

A formal "After Alvey" committee, chaired by Sir Austin Bide, has already been set up and will report in the autumn. Submit your evidence to Sir Austin, said Pattie: "no decision has been predetermined" and "real decisions" will be made. But as one iconoclast at the meeting put it, "can any number of collaborative programmes be a substitute for the rationalization of Europe's information technology industries?" Without markets and companies of the size found in United States and Japan, can Europe's excellent research ever be successfully exploited?

Alun Anderson

Chinese science

Legal protection for scientists

CHINA is to have a new law to protect societies from "outside interference". Addressing the third national congress of the Chinese Association for Science and Technology (CAST) last month, Song Jian, minister in charge of the State Science and Technology Commission, noted that the proposed law would give "official status to scholarly societies and define their role". It would regulate their relationship with the Communist Party, the government and state-owned collective and individual enterprises. Song said, as well as guaranteeing that their work could proceed "along normal lines".

China has 138 learned societies and organizations with 1.8 million members, who, in their turn, according to Song, are "in touch with a further five million scientists and technicians". The need for legal protection for scientific and learned research has been much discussed in the Chinese media during the past two months, in connection with the thirtieth anniversary of the launching of the "double hundred" policy ("Let a hundred flowers bloom, let a hundred schools of thought contend") which in recent years has been restored to official favour. The Constitution of the Peoples' Republic of China (Article 47) stipulates that "citizens have freedom to engage in scientific research, literary and artistic creation and other cultural activities", but this did not save scientists and scholars during the cultural revolution. Promulgating a specific law to cover learned activities, however, is felt to be sufficient, in the words of the People's Daily, to "ensure the implementation of the 'double hundred' without any intervention by or hindrance from either 'leftist' or 'rightist' tendencies".

The new law, and the "double hundred" policy itself will not give the scholars total independence. Social scientists, economists and philosophers will be allowed, within their learned environments, to investigate and consider non-Marxist theories. If they are asked to provide recommendations for practical implementation in production or society, however, they must base their proposals on sound Marxist principles. The natural scientists come off somewhat better, since, according to the Peoples' Daily and other leading commentators, the natural sciences can only flourish properly when kept clear of misleading ideological and philosophical labels. Frequent reference has been made recently to the Qingdao genetics forum of August 1956, which broke the monopoly of Lysenkoism in China as the exemplar of the proper "contention" of scientific ideas. Vera Rich

Why not move RGO to Manchester?

SIR—Alun Anderson's News article (Nature 321, 799; 1986) on the move of the Royal Greenwich Observatory (RGO) neglected to report that the Science and Engineering Council (SERC) also considered the possibility of moving it to Manchester. In fact, Manchester presented a powerful case, so why will RGO not move here?

SERC found the merits of Cambridge and Manchester to be finely balanced but simply considered the Cambridge case "to be even stronger". A world-beating centre of excellence is clearly what it was seeking, but that should not automatically favour Cambridge. The recent review by the University Grants Committee (UGC) rated Manchester's Physics and Astronomy Department, including Jodrell Bank, as outstanding, and here RGO would have formed the nucleus of a centre every bit as excellent as that we can expect in Cambridge. Did a beleaguered regional university just lose to the charisma of the old establishment?

An important inconsistency in the council's reasoning is that while claiming to be planning for the 1990s, it has allowed itself to be unduly influenced by the short-term consideration of minimizing disruption. Moreover, it does not give any reasons why the disruption caused by a move to Manchester should exceed that of a move to Cambridge. Could this be prejudice by the staff of RGO itself?

Alun Anderson's worries about costs are very relevant, but here Manchester had a strong advantage which was ignored. Construction of a new building to house RGO in Cambridge was apparently considered no more expensive than minor internal alterations to the suitable vacant premises in Manchester.

The council blithely asserts that both Manchester and Cambridge "have excellent communications" - sweeping Manchester's overwhelming superiority in this regard under the rug. The RGO staff will have to make regular trips to the new observatory in the Canary Islands; Manchester's international airport offers frequent direct flights and is just 20 minutes' drive from the university, whereas Cambridge to Gatwick airport is a long and awkward journey. It will be many years before Stansted will offer a service as good as already exists from Manchester. In addition, Manchester's rail and motorway connections to the rest of the country are far superior, which, together with its more central geographical location, would make RGO here much more readily accessible to astronomers around the country.

But the most disappointing aspect in my view is the missed opportunity for some positive action to redress the north/south

economic imbalance. The number of new jobs at stake is rather small, but the relocation of an influential and sophisticated scientific research organization to the north-west would be a morale-boosting statement of confidence in northern science and industry. Its demands for local specialized high technology, computer software and so on would be of much greater industrial benefit here than in the already thriving area around Cambridge.

We may never know what clinched the decision in favour of the old university and the south. But we should be told because it caused extra expense and could be to the lasting detriment of British astronomy outside Cambridge.

Prehistoric protection

SIR—The letter by Fernández and others' on radon in the Altamira cave shows how lax the standards of radiation safety were in Europe before 10,000 BC. Assuming that they worked a 40-hour week, I estimate that the palaeolithic painters received an annual radiation dose of 130 mSv from radon daughters. This would not be permitted under the Euratom legislation to which the European Community is now subject²: the dose limit for workers is 50 mSv in a year and indeed all exposures must be kept as low as reasonably achievable.

Speaking up

Sir—David Swinbanks (*Nature* **321**, 374; 1986) seems to doubt the relevance of the speech I made when accepting the Japan Prize.

An example of scientists not speaking up in time was the destruction by a Christian mob, around AD 415, of the famous library in Alexandria. That event set back civilization 1,000 years.

If third-century scientists had been able to enlighten the public, and if the government and the clergy had spoken out loudly and clearly at every opportunity, that set back would not have occurred. If we do not speak up now, our civilization may be destroyed for more than 1,000 years.

While in Japan, I learned that the United States is expected to provide a great deal of money for research for the Australia

Strategic Defense Initiative (SDI) by West Germany (25 per cent), Great Britain (18 per cent) and Japan (13 per cent). The preliminary budget is \$60,000 million simply for research; development is not mentioned. You cannot blame the British Prime Minister for not refusing a subsidy to the British economy of 18 per cent of \$60,000 million.

President Dwight Eisenhower warned against the military-industrial complex, which has a momentum of its own. It has now extended far beyond the United States.

I also said in Japan that President Reagan has a better chance of achieving a nuclear freeze and a reduction of the nuclear arms race than any previous president. He should be told what scientists feel.

W.J. KOLFF

Screwworm fly

SIR—In the past twenty years, despite one or two minor setbacks, the New World screwworm fly, Cochliomya hominivorax, has been eliminated from the southern United States and all but the most southern areas of Mexico. It is difficult to accept that this is due, as suggested by J.L. Readshaw (Nature 320, 407; 1986), solely to climatic conditions adverse to the survival of the fly during this period. It is surely more than a coincidence that this occurred concurrently with the major sterile insect release method eradication campaign in the region.

This campaign, by the US Department of Agriculture, has apparently eliminated this major agricultural pest, which caused losses of many million dollars to cattle ranchers in the southern United States and Mexico.

A related species, Chrysomya bezziana, widespread in South-East Asia and Papua New Guinea, is one of the most serious exotic animal disease threats to Australia. The United States has been most generous in sharing sterile insect release technology. This has enabled Australia to develop methods which it is hoped will be effective in eradicating any incursion of Chrysomya bezziana into this country. Whatever the beneficial effects of climate to the North American programme, the tropical climate in northern Australia has convinced us that rapid application of the US technology would be our major defence response.

Anti-darwinism in Japan

SIR-L.B. Halstead's article1 on the socalled Imanishi phenomenon, the popularity of the writings of Kinji Imanishi, emeritus professor of Kyoto University, among intelligent laymen in Japan, attempts to relate the phenomenon to the character of Japanese society and its scientific community. Imanishi points out that the competition and selection in Darwin's view of nature derive from the cultural and religious ethos of Western paternalistic society, whereas the Japanese view is maternal, one that sees the inherently harmonious nature of the living world.

After holding a visiting professorship at the department of geology and mineralogy of Kyoto University, Halstead explained the Imanishi phenomenon by pointing out that the present world, Japan in particular, is demonstrably a world of competition, struggle and disharmony. In such a world or society, Halstead writes, "Imanishi's theory can satisfy the dreams and aspirations of people in a desperate rat-race, serving as a dream-scape sentimentality. Unhappily it has no place in scientific understanding of the real world."

Halstead's observation is rational, axiomatic and persuasive. Yet it creates a certain disharmony in the minds of "average laymen" in Japan. It reminds us of Niels Bohr, who extended his complementarity principle in quantum mechanics to the realm of human concerns beyond natural science. He states that the rational scientific approach is only one way of dealing with the world around us. A given approach seems fragile and senseless when applied within the framework (cultural tradition) of another, but is forceful and convincing within its own frame².

One of the central concepts of Imanishi's evolution theory, the principle of life-style partitioning which later evolved into the idea of the harmonious nature of the living world, arose out of his early research on aquatic insect larvae, mayflies in particular, in freshwater streams. On the basis of recent researches in freshwater, marine and terrestrial habitats in experimental ecology which demonstrated that interspecific competition takes place in 90 per cent of all cases studied, Halstead claims that the statistical foundation of Imanishi's theory no longer stands. He adds: "this seems to have little effect on either the standing or on the public reception of Imanishi's ideas so long as he states he is not an ecologist, since then ecologists cease to discuss his theories. When Imanishi further states he is not a scientist, fellow scientists no longer feel there is any need to discuss his ideas." Thus Halstead concludes his article with the statement that vigorous debate and scientific confrontation are not part of the cultural tradition in Japan"... originality and innovation flourish in secret enclaves — Kyoto University saloon and coffee houses - beyond the experience of the ordinary Japanese, condemned, as they are, to the rigid authoritarian feudal society that masquerades as one of the advanced nations of the world."

My understanding is different. When Imanishi states he is not an ecologist, he is warning with A.N. Whitehead³ that the narrowness in the selection of evidence in science is the chief danger to the construction of a holistic world view. When Imanishi states he is not a scientist, he is proposing that the ultimate concern and responsibility of a scientist should be to free contemporary intelligent laymen from their cultural fragmentation by making them more conscious of the way in which art, morality, religion and science have become specialized, censorial, constrictive to the unbroken wholeness of our cultural experience.

As Halstead points out, the fundamental divide in man's view of the evolution of life has been the degree of emphasis placed either on observed variations among individuals or on the features held in common. Then the harmonious nature of the living world exemplified by the phenomenon of altruism and habitat segregation becomes susceptible to an explanation in terms of natural selection. It would then be a responsibility of a careful scientist to try to replace words such as competition and selection by more objective terms or words that do not change the essential scientific tenets of darwinism but greatly change their aesthetic, moral and religious connotations. Without a critical usage of the words, the notion of the survival of the fittest, for example, would become a tautology of the selection of the selected or the survival of survivors1.

It is encouraging that the progress of molecular genetics over recent years has developed new concepts such as evolution by gene multiplication' and concerted or coincidented evolution which are not inconsistent with Imanishi's ideal of the evolution of the harmonized holospecia in which all the individuals of a species evolve simultaneously when the time becomes ripe.

Needless to say, we are only beginning to understand the origin and the evolution of life. At present, we do not even know whether the evolution was gradual or sudden. As a rule, darwinian selection is more important over long periods of time and Motoo Kimura's picture of molecular evolution by random statistical fluctuation without selection (neutral theory)⁷ is more important over short periods. In reality the evolution must have been a complicated process with incidents of rapid change (punctuated equilibrium - development in bursts of evolution)' separated by long periods of slow adaptation.

Finally, one of the persistent concerns of intelligent laymen in Japan since the time of the Meiji Restoration (1868) has been why science in the modern and current sense emerged in a restricted area of the world (Western Europe) and in a restricted period of time (early Middle Ages). It is commonly held that the synthesis of the Judeo-Christian conception of open-ended time and the Benedictine Order's motto "laborare est orare" lent progress and activism to the course of the history of Western civilization. We agree with Halstead that one of the secret enclaves of Kvoto University besides coffee houses, the Institute of the Humanities, where Imanishi's basic ideas and concepts took shape, was modelled after a medieval monastery in feudal Europe, though not of genuine Benedictine style.

Roman Khesin-Lur'e

SIR-Vera Rich, in her comments on the Lenin prizes for science in the Soviet Union (Nature 321, 6; 1986), was very sceptical about the merit of this award given to Dr R. Khesin-Lur'e, merely because the award citation dated his publications in biochemical genetics from 1960 when "Lysenkoism was then in full swing". Rich also stated that "it would be interesting to know where Khesin Lur'e published his work at that time, and what part, if any, he played in the overthrow of Lysenkoism". Unfortunately, my old friend R.B. Khesin-Lur'e is unable to answer these questions. The prize was given to him posthumously. Because he was indeed a very prominent scientist, I hope that my brief reply may serve as a short obituary.

Roman Beniaminovich Khesin-Lur'e was born in 1922 and graduated from Moscow University as a geneticist in 1945. His PhD study was carried out under the supervision of the prominent Soviet geneticist A.S. Serebrovsky. In 1948, immediately after Lysenko's "coup", Khesin-Lur'e was dismissed from Moscow University. In 1949-53 he worked as an ordinary technician at the Institute of Biological and Medical Chemistry in Moscow, and in 1954-59 as a lecturer in biochemistry at the Medical Institute in Kaunas. In 1959, he started research work as senior scientist in biochemical genetics at the biological division of the Institute of Atomic Energy in Moscow, where Academician Igor Kurchatov gave protection to many Soviet geneticists who were not able to find work in the academy system or in colleges of higher education. From 1978, Khesin-Lur'e (who is better known in Soviet literature simply as Khesin) worked at the Institute of Molecular Genetics of the Academy of Sciences of the USSR and was, in fact, a founder of this institute.

It is enough to look through Chemical Abstracts for 1959-65 to find out that R.B. Khesin was able to publish many of his works during the period of Lysenko's domination. They were published usually in journals, such as Biochimija, Medizinskaya Khimija, Zhurnal Vsesoyznogo Khim. Obshestva and in different volumes, such as Aktual'nye Voprosy Sovremennoi Biokhimii, starting from Vol. 1 in 1959 and covered many subjects relevant to biosynthesis of proteins and nucleic acids. In 1960, Khesin published his well known (in the Soviet Union) book Biokhimija Tsytoplasmy (Biochemistry of Cytoplasm), which was published by the publishing house of the Academy of Sciences of the USSR. Khesin-Lur'e did play a very important role in "the overthrow of Lysenko" and did so primarily by his honest and intensive research in an extremely difficult situation. He died from

cancer in 1985, very soon after he was i nominated for the Lenin prize.

Lenin prizes in science are not international and the evaluation of scientific merit for them is, of course, a matter for Soviet scientists to decide. The very fact that Vera Rich has apparently never heard the name Khesin-Lur'e before is certainly not sufficient reason to doubt his contribution to science and his integrity as a scientist.

Environmentalism

SIR-David Pearce rightly criticizes the nuclear industry in his review of Tony Hall's book, Nuclear Policy: The History of Nuclear Power in Britain, for having neither the traditions nor the capabilities to handle "environmentalism" when it emerged as a popular and political force. The industry was not alone in failing to appreciate the threat of this movement. It has taken some time for the true motivations of some "environmentalists" to emerge. Many of them seem to be seeking some sort of non-industrial Arcadia irrelevant to the needs of today's world, dominated by the problems of developing countries attempting to achieve some improvement in their living standards in the face of relentless pressures from population growth.

For example, Edward Goldsmith in an editorial in the Ecologist asks "How are we to power our expanding industrial society?". He considers the prospects for oil, coal and renewable sources of energy and concludes "The answer is that there is no alternative (to nuclear power)... no nuclear power — no industrial society... the nuclear power station has become the symbol of the industrial way of life... The industrial way of life is squalid, mediocre and unfulfilling. Progress is an illusion.'

The consequences of such views are well illuminated by J. Gordon Edwards' who points to the enormous amount of damage done by so-called environmentalists using as an example the DDT story. where concern about trace quantities of this material has had untold harmful consequences on malaria eradication programmes.

The world's problems may be soluble through the continuing application of science and technology that has already led to dramatic improvements in infant survival, public health and life expectancy, to a transformation of India from a continent threatened by starvation to a net food exporter, and to the harnessing of nuclear energy to enable the world to survive the depletion of its fossil fuel reserves and avoid the risks of climatic

change from their consumption. They will not be solved by the pursuit of rural Utopias inconsistent with today's population and its aspirations.

The Chernobyl accident should result in a major re-examination of the safety of nuclear plants throughout the world. We must ensure that the lessons of the accident are learned and applied, as happened, at least in the West, after Three Mile Island. But the predictable calls for a run-down of the world's nuclear programmes as a result of Chernobyl is as sensible as a call for the world to do without agricultural chemicals as a result of Bhopal.

 Goldsmith, E. Ecologist 6, 310 (1976).
 Gordon Edwards, J. Nature 320, 391 (1986).

Sir—The leading article "What future for nuclear power?" (*Nature* **321**, 367; 1986) contained criticisms of Western environmental movements and impugned the motives of their membership.

Surely imprecation via an examination of motives as a substitute for argument is slightly insulting to the readers of Nature or any other journal bent on the promotion of serious discussion.

Apart from the fact that criticism based on an examination of motives is irrefutable in practical terms, it also substitutes mud-slinging for discussion. It is tempting to suggest that the aspiration of the mudslinger is that some of the mud may stick. But mud-slinging merely obscures issues and never contributes to serious debate.

The Western environmentalist movement has raised serious doubts, based on cogent arguments, about the efficacy and safety of nuclear power. It is these arguments that should be addressed; the reasons why the participants raised them, apart from concern with efficacy and safety, are of little significance.

Focusing on this matter, at the expense of arguing your case, results either from the arrogant assumption that environmentalists are of little consequence because of their populist origins and so their views on nuclear power must also be of little consequence, or a tacit recognition that the environmentalist argument presents problems for those who support the nuclear power programme. If the latter, why not admit it, and if the former, shame on you!

Looking for gravitational errors

The idea that there may be forces between macroscopic objects other than those caused by gravity is no longer an outrage. But precisely what is meant remains unclear.

THERE is always a special attraction in the discovery in the published literature of a surprising truth that other people have overlooked. This is no doubt one of the extra reasons why close attention was paid to the announcement earlier this year, by Fischbach et al. that the Eotvos experiments, first published in the 1920s and widely regarded since then as a proof that the gravitational force between massive objects is independent of their chemical constitution, concealed evidence that there is a force other than gravity between ordinary material objects (see Nature 319, 173; 1986). The proposal is not nearly as heterodox as it may at first have seemed. Most obviously, there have repeatedly been suggestions that the constant in Newton's law of gravitation (called G) is smaller when measured in laboratoryscale experiments than the value required to account for geophysical phenomena.

The article by Fischbach et al. originally appeared in Phys. Rev. Lett. (56, 3; 1986). The essence of its conclusions was that the published errors in the Eotvos measurements of the gravitational attraction between different kinds of substances (carried out with a torsion balance) could be accounted for if there is a force with a characteristic range of about 200 m whose strength depends on the baryon number (only roughly proportional to the mass) of the interacting materials. Now the same journal has published three papers which take the argument a little further, but which have the virtue of suggesting how the matter might be settled.

It is not really surprising that effects such as that described by Fischbach et al., if real, should have been overlooked for half a century. In spite of the exquisite accuracy with which it is possible to describe gravitational systems such as planets in orbit about a central mass such as the Sun, these successes cannot exclude the possibility that short-range forces between material objects may exist. Moreover, in systems such as these, where only relative masses matter to a first approximation, uncertainties may be arbitarily accommodated in either G or in the planetary and solar masses. This is one reason why it is notoriously a minor scandal that G is, even now, known a little less accurately than one part in 10⁵.

For the sake of clarity, it is worth recalling the form in which the Fischbach result is put. Most simply, G can be set equal to G_0 , the value of the gravitational constant ensuring that the centres of gravity of the two objects do not change with the oscillation). The oscillation itself was intended to provide a signal of known frequency

at infinity, multiplied by a factor differing from one by the addition of a relatively small distance-dependent exponential term of the form $\exp^{-(rl)}$. The distance lthen represents the scale over which departures from strict compliance with Newton's inverse-square law may be expected. The supposed constant by which the exponential factor is multiplied is a measure of the strength of the non-newtonian effect. The characteristic length was estimated at 200 m, with a possible error of 50 m in either direction. The constant of proportionality is most distinctive for being negative, meaning that apparently gravitational forces are smaller at smaller distances, or that the extra force is repulsive; its magnitude is such as to affect gravitational attraction by a few tenths of a per cent at zero distance.

It is also, of course, possible that some of the uncertainty in the value of G arises because of attempts to reconcile irreconcilable measurements of gravitational forces on the very large scale and the very small. If, indeed, there is an extra force of interaction perceptible over distances of a few hundred metres only, laboratory measurements of gravitation, going back to Cavendish, will differ systematically from those inferred from astronomical observations. Certainly one of the consequences of the reinterpretation of the Eotvos experiments by Fischbach et al. is that future attempts to narrow the errors in measurements of gravitational force will diligently segregate short-range from long-range measurements.

Two of the clutch of three articles now published by Physical Review Letters are, like Fischbach et al., of an archival character. Both David A. Neufeld of Harvard University (56, 2344; 1986) and S. Nussinor of Tel Aviv University (56, 2350; 1986) go back to the records of an experiment by L.B. Kreuzer first published in 1968 (Phys. Rev. 169, 1007; 1968). The objective was to carry out a kind of dynamical equivalent of Cavendish's direct measurement of the gravitational force between two static objects. For this purpose, Kreuzer used as gravitating masses containers with equal volumes of liquid within which were embedded oscillating masses of density equal to that of the surrounding fluid (which is a neat way of ensuring that the centres of gravity of the two objects do not change with the oscillation). The oscillation itself was intended

that, with luck and clever design, might be picked out easily from among the inevitable noise. Kreuzer's objective was to distinguish between the "passive" and "active" or dynamic gravitational fields caused by moving masses; his conclusion was that they could differ by, at most, one part in 20.000.

Both Neufeld and Nussinov now point out that the same measurements can be interpreted in terms relevant to the new Fischbach force. For, by good luck, the fluid in the Kreuzer experiment was a mixture of halogen-containing hydrocarbons different in chemical constitution from the solid rods of Teflon suspended in them. The difference is enough to account for a significant difference, for each unit mass. in baryon number, which is a measure of the content of protons and neutrons in a material (whereas the mass of the same material is the same quantity modified by what the nuclear physicists call the packing fraction, or the nuclear binding energy, of the elementary constituents of the materials).

Both Neufeld and Nussinov now argue that the Kreuzer measurements probably provide a more sensitive test of the implications drawn from the Fischbach analysis than an attempt to repeat the Eotvos experiments as such. Indeed, on various interpretations of the Kreuzer measurements, the intermediate-range field of force suggested by the re-analysis is already a little beyond the bounds of likelihood. Neufeld suggests that if the Eotvos measurements are to be repeated. it would be most profitable to do so at the foot of a tall cliff, where the effects of natural gravitational asymmetry would be most apparent.

P. Thieberger from the Brookhaven National Laboratory (56, 2347; 1986) is even more lyrical on the subject: repeating the Eotvos measurements at the bottom and the top of a tall cliff could be the most sensitive measurements yet bearing on the existence (or otherwise) of the intermediate force. (The University of Bath, sited on the top of such a cliff, is well placed, among others.) Given this enthusiasm it is certain that there will now be a host of proposals for the re-measurement of gravity by classical devices. The driving force may be the prize of pinning down the intermediate force. It must be hoped that one by-product will be the even more important definition of an accurate value John Maddox

Immunology

T-cell receptor: gamma gene product surfaces

from Miranda Robertson

THERE are various phenomena in cellular immunology that might demand a second antigen receptor on the surface of T lymphocytes; and as a T-cell specific receptor gene not encoding any part of the known antigen receptor, the gamma gene might have been expected to account for one of them. In fact, however, as has been remarked at intervals in these pages^{1,2}, it has been extraordinarily difficult to find out what the gamma gene is for; and until now, no protein product had been isolated to provide clues. On pages 145 and 179 of this issue34 two groups report the detection of the gamma gene product in a receptor complex on the surface of human T lymphocytes; and a third paper shortly to appear elsewhere' describes what is almost certainly the same putative receptor but without the evidence that it contains the gamma chain. The data in these reports suggest that the gamma gene is expressed on a small subset of circulating T cells; but there is no obvious way of fitting the gamma chain into any of the immunological phenomena still awaiting a biochemical basis. Before explaining how the receptor came to be detected and why it is difficult to reconcile with any of the roles envisaged for it, I shall briefly recapitulate what is known of the genes encoding the antigen receptor of T cells.

Of three functionally defined subsets of T cells, two — the helper and cytotoxic cells - are now known to express a receptor that is a heterodimer comprising one alpha and one beta chain, each encoded by a gene that is assembled by somatic rearrangement from a large and diverse pool of separate gene segments. This device for generating combinatorial diversity is familiar from immunoglobulin genes and seems to be the hallmark of those surface structures of lymphocytes that are responsible for specific antigen recognition. It is by that criterion alone that the gamma gene has been presumed to participate in the specific recognition of antigen.

The gamma gene was discovered fortuitously in the course of an attempt to isolate the alpha-chain gene (for which it was mistaken), and seems to be essentially similar in structure and organization to the alpha and beta genes, though with significantly more limited variability. There is no firm evidence that its expression is associated with any particular functional subset of T cells; and indeed in most mature T cells it is abortively rearranged—that is, the assembled gene segments

give rise to a transcript that cannot be translated into protein. This and the fact that it seems to be transcribed at relatively high levels early in thymic ontogeny have led several people to focus on the possibility that the gamma gene product has a specific role early in the ontogeny of T lymphocytes when it is believed that T cells 'learn' their unique pattern of dual recognition. The crucial feature of the Tcell receptor is that it is designed, or selected, or both, so as to recognize antigen only when it is associated on the surface of a cell with a molecule encoded by the major histocompatibility complex (MHC). This means T cells must be capable of activation by binding 'self' MHC when it is associated with antigen, but not when it is on its own. If the gamma chain plays a part in the development of this so-called MHC restriction then it is pivotal to the understanding of cellular immunity.

At this point it is only fair to say that the interesting findings described in the three papers I have mentioned earlier give no particular indication of any such role. The findings themselves are as follows.

The assumption from which all three groups started was that any antigen receptor on a T cell would probably be coexpressed with T3. T3, a multi-chain complex expressed on all T cells, is believed to be responsible for transducing the activation signal when the receptor heterodimer binds antigen. It is closely but noncovalently associated with the alpha-beta heterodimer and any mutation that prevents the appearance of the receptor heterodimer also prevents the appearance of T3 (ref.6). Nonetheless, there are lymphocytes that express T3 in the absence of the alpha and beta chains: they seem to account for about 3-8 per cent of peripheral blood lymphocytes (PBL)3.5. The presumption is that in these cells T3 may be co-expressed with some other receptor, for which indeed some evidence has already been reported'.

The biochemical definition of the receptor complex has however become possible only with the availability of large numbers of these relatively rare cells. As they report in this issue, Brenner et al.' succeeded in growing two T3+ alpha-beta cell lines from the PBL of immunodeficient patients (in normal individuals they are rapidly overgrown by alpha-beta cells); also in this issue, Bank et al. report the cloning of a cell with this phenotype after having selected for T4 T8- cells

(believed to be immature thymocytes); and Weiss et al.5 found a T3+ alpha-betaleukaemia. Much the most detailed biochemical analysis is that of Brenner et al... who report that their cell lines (which are 50 per cent T4-T8- and 50 per cent T4 T8⁺) express T3 in association with two chains: one of relative molecular mass 55,000 (55K) that binds antibodies raised against synthetic peptides representing gamma gene sequences; and a 40K peptide which they designate the delta chain. Bank et al. have a heterodimer in which a 60K protein is associated with a 44K chain that is recognized by the anti-gamma antibodies; and Weiss et al.5 find only a single 55-60K chain which they have not yet tested for reactivity with anti-gamma antibodies.

Clearly there are some discrepancies in the data from the three sources; but they are probably trivial. The difference in the size of the gamma chain identified by Brenner et al. and that of Bank et al. may for example be due to differences in glycosylation. On the other hand, the failure of Weiss et al. to find a second chain for their putative receptor is not surprising: it is not always easy to detect both chains of the established alpha-beta heterodimer; and besides, Brenner et al. and Banks et al. find that the gamma chain is not disulphide-linked to the second putative receptor chain. This distinguishes the new receptor complex from any other antigen receptor and may encourage speculation about the formation of alternative complexes between gamma and, say, beta chains; which brings us to the question of what the receptor is for. Only Bank et al. have functional data: they find that anti-T3 antibodies can induce both cytotoxicity and interleukin-2 secretion in their cloned cells, which thus seem to have the expected attributes of a normal T cell.

There are two cell types still in search of a receptor: natural killer (NK) cells, which may be related to T cells; and suppressor T cells. Do these data fit either of them? NK cells, like the cloned cells of Bank et al., have a T8-T4 phenotype and they are of course cytotoxic; but there is good evidence that they do not transcribe gamma genes.

Suppressor cells belong to an elusive regulatory subset of T cells that do not express the alpha-beta heterodimer that is common to the better-established helper and cytotoxic subsets. Might a gamma-delta complex be the suppressor receptor? Because of the rather ill-defined nature of this subset it is hard to rule this possibility out; but suppressor cells might be expected to constitute more than 3-8 per cent of PBL, and there is no obvious reason why, if cytotoxic and helper cells can use the same pool of receptor genes, suppressor cells should need a different one.

Finally, what of the postulated role of the gamma chain in T-cell ontogeny? It

cannot be excluded. But it is very difficult to imagine how an immature thymocyte expressing a given gamma-delta heterodimer could be selected for the properties of a subsequent alpha-beta heterodimer: so gamma would have to be co-expressed for at least some of the time with alpha or beta or both (and indeed a scheme of this sort is envisaged in one of the theories on the early role of gamma9); however there is no evidence that this occurs and Brenner et al. and Bank et al. know there are no functional alpha or beta transcriots in their cells while Weiss et al. find beta transcripts but there is no evidence that they are functional. It remains possible nonetheless that the alpha and beta genes are functionally rearranged later and a two- (or one-and-a-half10) receptor system might operate at some stage in ontogeny.

Co-expression of gamma and the alphabeta heterodimer as the basis for dual recognition of antigen and MHC in mature T cells¹⁰ can probably be excluded

because dual specificity for MHC and antigen can be conferred by transfection with the alpha and beta genes alone".

One would have thought there was already quite enough cellular immunology to satisfy any demand for a phenomenon to fit a molecule; but it begins to look as though to understand the gamma gene it may be necessary to invent still more of

Particle physics

Particles and the Universe

from Neil Turok

COSMOLOGY is now the main arena in which fundamental theories of particle physics can be tested — an exciting stream of data on the large-scale structure of the Universe is just beginning to appear. It is also interesting that particle physics experiments designed to detect the 'dark' matter in the Universe directly should become operational in the next few years. Developments in these areas were discussed at a recent meeting*.

The most recent observations support earlier indications that the Universe has a lot of structure on quite large scales. This is very important for theories of particle physics. In most theories the matter has not moved about much on these scales since the Big Bang and so the observations provide a fairly direct 'window' on what the very early Universe was like.

Five years ago, the Bootes void, a region about 60 Megaparsecs (Mpc) across apparently devoid of bright galaxies was discovered. On the average, such a region would contain a thousand galaxies. More recently it was found that clusters of galaxies are themselves significantly clustered on a similar scale. Now two further observations support the existence of largescale structure.

The first, discussed by Joseph Silk in a recent News and Views article (Nature **320**, 12; 1986), is the result of measuring redshifts of galaxies in a thin slice of the Universe out to 150 Mpc. The measurement reveals a 'foamy' distribution of

Second ESO/CERN symposium: Cosmology, Astronomy and Fundamental Physics, Munich 17–21 March 1986.

galaxies, most of them lying on sheets surrounding large, almost empty holes of radii up to 50 Mpc. A problem with these data is that no correction has been made for peculiar velocities — the redshifts are simply interpreted as being the result of Hubble flow. Peculiar velocities produced by local gravitational infall can produce such sheets as artefacts. But even if this is the explanation, the data seem to indicate large coherent velocities in the distribution of galaxies over large scales.

The second observation confirms this point of view. Richard Bond and Sidney van den Bergh described in a recent News and Views article (Nature 320, 489; 1986) a large region of radius about 50 Mpc around our Galaxy that appears to be moving coherently with a velocity of about 1,000 km s⁻¹ relative to the microwave background. This is a significant fraction (about a fifth) of the Hubble flow on that scale.

These observations are bad news for the most popular current theory of the origin of fluctuations in the Universe. This is based on the notion of 'quantum fluctuations' produced by a field in the process of causing an inflationary stage in the very early Universe. One of the early successes of the inflation model was that it predicted a reasonable spectrum, the Z'eldovich spectrum, for the fluctuations. However, inflationary models require an artificial adjustment of parameters to very small values to give the perturbations a reasonable amplitude. There was consensus at the meeting that although inflation re-

mains a very good idea, no aesthetic model in which it is realized has vet been

Quantum fluctuations have several attractive aspects for cosmologists. They are linear, adiabatic and have a gaussian probability distribution. So it is comparatively easy to calculate their effects. Inflation clearly predicts that the cosmology density parameter Ω is very close to unity. In conjunction with arguments from nucleosynthesis, this requires the Universe to be dominated by non-baryonic

The first models to be looked at in detail were universes dominated by hot dark matter such as massive neutrinos, which free stream out of dense regions and erase perturbations on the scale of galaxies. As a result galaxies form much too late. Hot dark matter models appear to predict fluctuations in the cosmic microwave background marginally larger than the observational upper bounds (G. Efstathiou, Cambridge). But some criticism was made of the statistics used in obtaining the bounds (F. Melchiorri, Rome); there is agreement that the bounds usually quoted are too low by a factor of at least two.

The next models were universes dominated by cold dark matter, for example, axions, photinos or quark 'nuggets'. These models have the opposite problem (J. Primack, Santa Cruz). Although galaxies formed early enough, there is very little structure on large scales - in particular the correlations between clusters of galaxies are hard to understand. One way out is to invoke biassing — the idea that visible matter (stars) formed only at the peaks of the underlying matter distribution. Galaxies formed above some threshold, clusters formed at a higher threshold and so on. With a gaussian distribution, this increases the correlations of clusters, although not on scales as large as 50 Mpc. Voids are another possibility. Here, the large-scale structure appears as a statistical artefact of our seeing only a small fraction of the matter in the Universe. The underlying distribution of matter is very smooth, and coherent velocities on the scales which have now been observed were less than 160 km s . With a large degree of confidence, these models now seem to be ruled out.

The main alternative theory of the ongin of structure involves cosmic strings. relativistic defect lines which are predicted to form in the early Universe by many Grand Unified Theories and superstring theories. Loops of cosmic string chopped off a network seem to have just the right properties to seed the formation of galaxies and clusters of galaxies (see Hogan, C. Nature News and Views 320, 572; 1986). Interestingly, cosmic strings are able to produce the required small- and largescale structure in either hot or cold dark matter universes. In the former, small loops of string survive the free streaming and go on to seed galaxies, whereas in the latter, larger loops provide the large-scale structure. Cosmic string theories produce a correlation of clusters of galaxies remarkably similar to what is observed. Detailed calculations of the large-scale coherent velocities produced by cosmic strings have yet to be made. With hot matter these will almost certainly be large enough, and even with cold matter the fluctuations on large scales caused by large loops are much larger than with quantum fluctuations.

There remains the crucial question of the dark matter. Evidence from galactic rotation curves and from the dynamics of galaxy clusters suggests that dark matter does exist, but this is quite consistent with the simplest explanation: an $\Omega = 0.1$ Universe dominated by large planets (Jupiters) (M. Rees, Cambridge). But recent results from the infrared survey IRAS give a measurement of Ω on very large scales of around unity (M. Rowan-Robinson, Queen Mary College, London). If confirmed these results will reinforce ideas of the fundamental simplicity of our Universe, and the question of what the nonbaryonic matter is will become more

Particle physics has already come up with a plethora of candidate particles for the non-baryonic matter, none very well motivated. The massive neutrino received a lot of interest after Lyubimov et al. (Phys. Lett. 94B, 266; 1980) reported a mass for the electron neutrino in the cosmologically interesting range, around 30 eV, some time ago. However, a recent

experiment using more sophisticated apparatus disagrees with this value, setting an upper bound of 18 eV on the electron neutrino mass (K. Winter, CERN). The possibility remains that the Universe is dominated by the (very likely heavier) muon or tao neutrinos.

Some very interesting new ideas for detecting cold dark matter particles have been proposed recently (P. Smith, Rutherford Appleton Laboratory). The axion is probably the best candidate, being very light (about 10^{-s} eV) and very weakly coupled to other matter. Axion decay into two photons can be stimulated by a tuned oscillating field in a resonant cavity, and several experiments to detect axions by this method are under way.

Small pure crystals or lumps of superconducting metal can be used to look for more massive (about 10-1,000 GeV) weakly interacting particles like photinos or sneutrinos. Such a particle colliding with 1 mm³ of silicon at 50 mK would cause a recoil in the nucleus it collided with sufficient to heat the crystal by 5 mK. With existing technology, this can be detected with an accuracy of 1 per cent. A detector containing 1kg of such crystals would be expected to see from 1 to 1,000 events per day if these particles dominated the Universe. The experiments will probably take 2-3 years to set up and will open up a new area of particle physics; at the very least they will provide invaluable information on what the dark matter is not.

Archaeology

Towards a scientific approach

from Patricia Phillips

ARCHAEOLOGY, the study of our past, developed in a humanistic framework, although basic methods such as observation of stratigraphy were borrowed from contemporary sciences. Recently, more sophisticated techniques have been developed and refined to provide a basis for many types of archaeological investigation. But in the United Kingdom more money is needed to keep pace with current excavations and fieldwork and to apply the new techniques to the many artefacts and ecofacts generated by government-funded programmes over the past two decades. This is the message of a new report¹ archaeology must be science-based in fact, not just in name

Many archaeological finds, from whole sites to individual buildings, early industrial structures and assemblages of artefacts and ecofacts, fail to be exploited to their full scientific potential. Much more use should be made, both of established scientific techniques and of newly developed methods, to maximize the information from each archaeological find.

Readers of Nature will be familiar with some of the more recent applications of science to archaeology, such as refined radiocarbon measurement techniques permitting very small samples to be accurately dated. At the accelerator laboratory in Oxford, individual charred wheat grains from Danebury hill fort, England and from Mycenaean Greece have been successfully dated2. The European treering chronology, based mainly on German and Irish oaks, can be traced back more than 7,000 years', and small sequences of tree rings have been used to 'recalibrate' radiocarbon dates from the Neolithic period onwards4. Another dating technique, thermoluminescence, originally used on ceramics and ancient hearths, is being applied to burnt flint, and to windblown sediments: these applications offer new opportunities for dating on Palaeolithic sites, and are particularly useful beyond the present precision of radiocarbon (~ 40,000 years before present). One of the first examples was the dating of two burnt flints from the site of Terra Amata, Nice, to 230,000 years before present⁵.

Aerial photography on various scales is being intensively used by archaeologists. Satellite photographs are generally on too large a scale to be useful, but LANDSAT images have been used to trace broad aggradational features (ancient levee systems) in Mesopotamia⁶. Below-ground features showing up on oblique aerial photographs can now be mapped more precisely by using relatively simple computer programs, for instance, multi-point \ projective transformation7. Geophysical instruments have been refined and developed, and include soil-sounding radar, which has been tested at Sutton Hoo, and side-scan sonar, used in underwater archaeology8. Detailed air photographs or geophysical plots have increasingly been used as the basis for archaeological interpretation, since they are less costly than excavation. Although this is a valid exercise, especially for examining large landscapes, such interpretations need to be checked by excavation.

Where excavation does occur, automatic recording of information on microcomputers is becoming more widespread, and topographical survey before and during excavations has been revolutionized by the electronic distance meter. In 1984 this instrument was used to survey a Lincolnshire long barrow and adjacent excavation trench in only four hours.

Studies of past environments, in terms of soils, sediments, pollen grains and molluscs, are a standard feature of site investigations of all time periods. Increasingly sophisticated and precise techniques have been developed (for example, soil thin-sectioning and diatom analysis).

All the structures which archaeologists excavate, from scarcely visible shadows of postholes and pits to walls of brick or stone, can be characterized or finger-printed scientifically, although frequently the lack of funds prevents this from taking place. Some techniques, such as thin-sectioning or physical chemical analysis, are well established, but need to be expanded to all relevant raw materials in buildings and other structures.

New methods are also needed to study the composition of common artefact types, such as flint tools or some types of pottery, where extensive work using atomic absorption spectroscopy or neutron-activation analysis has only been partially successful in separating out source materials. Early metal artefacts are also difficult to characterize satisfactorily. However, their composition is becoming

better understood, both as larger series are investigated and with the application of lead isotope analysis. This relatively new method can identify the sources of ancient coins and metal artefacts. More recently, inductively coupled plasma spectroscopy has been used to characterize stone, pottery, metal and glass.

During the 1970s and 1980s the scanning electron microscope and its auxiliary tool, the electron microprobe, were increasingly used to investigate the structure and composition of archaeological artefacts and ecofacts, from crucibles and coin moulds to fragments of wood scabbard and sheepskin scabbard lining10. The scanning electron microscope is also useful as an addition to standard microscopy in microwear analyses. These studies of the polishes, striations and residues which indicate how a tool was used, and on what material, have expanded widely in western Europe since the mid 1970s. Although the high magnification of the analyses (at least 280 ×) restrict the numbers of artefacts that can be studied, the method is objective, and has allowed significant progress in the study of stone and bone tools. For instance, the method demonstrated that flint flakes found found beside a Neolithic trackway in the Somerset Levels, United Kingdom, were used to cut reeds and whittle wood".

New methods are being developed to age skeletons12 and to determine past diets. Blood grouping on ancient bone, to identify relationships between ancient mummified or buried bodies, a widely exploited technique, particularly in Hungary, has been applied to few individuals from British tombs. However, the publicity surrounding 'Lindow Man', whose 2,500-year-old body was found in a Cheshire peat bog, enabled a wide range of tests to be applied (from standard X rays and scanning electron micrographs to Xero radiographs, nuclear magnetic resonance, computer tomographic scans and surgery using a fibre optic endoscope) 13 . \square

Parasitology

Clandestine sex in trypanosomes

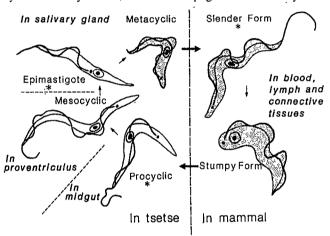

from Keith Vickerman

ALTHOUGH few biologists would question that eukaryotic organisms once needed sex to reach levels of cell complexity denied to prokaryotes, there is room for doubt over whether many unicellular eukaryotes have had cause to retain it. Indeed there is a complacent conviction among those who study them that a haploid genome and short doubling time enable the asexually reproducing protist to look natural selection in the face — and survive without the gene-shuffling benefits of meiosis and syngamy. So the demonstration of hybrid formation in sleepingsickness trypanosomes after transmission by the tsetse fly vector, described on page

A further source of genetic variation in trypanosomes may lie in the kinetoplast (mitochondrial DNA) close to the base of the flagellum (see figure). This unique structure contains about 100 20-kilobase (kb) maxicircles (corresponding to the mitochondrial genome in other eukaryotes) interlocked with several thousand 1-kb minicircles whose sequences alter during vegetative growth, providing another possible system of genome reassortment. The function of the minicircles (other than maintaining the network) is a complete mystery. Maxicircle deletions or disruption of the network are associated with loss of ability of the single mitochondrion.

> which is repressed in the mammalian host, to become activated in the vector.

> Trypanosomes ingested by the bloodfeeding tsetse fly embark on a long and complicated cycle of development multiplication, first in the vector's gut and later in its salivary glands (see figure)4. Hitherto the trypanosome cycle has revealed no obvious gamete or zygote stages. Yet Jenni and colleagues' find that

Developmental cycle of Trypanosoma brucei. Shaded areas, stages expressing variable antigen genes; asterisks, multiplicative stages.

173 of this issue, exposes a surprising and hitherto clandestine activity on the part of these important parasites, and one which calls for reassessment of several aspects of

One reason for doubting the existence of sexuality in trypanosomes was that these organisms have their own ways of generating genotypic diversity, regardless of sex, and these have received much attention in recent years. The tsetse fly-transmitted parasites have met the principal challenge to their survival in the blood of an antibody-producing host by evolving an elaborate genetic mechanism for repeatedly changing the antigenic nature of their protective glycoprotein coat2. Only one of 1,000-2,000 variable antigen genes is expressed at a time and expression can occur only at a chromosomal telomere. The switching process usually involves DNA rearrangements in order to get the new gene into the telomere expression site. These rearrangements provide a system of recombination and reassortment of variable antigen genes during asexual multi-

the mixture of two parental trypanosome stocks followed by tsetse transmission can result in stocks of non-parental phenotype which are heterozygous for parentalhomozygous isoenzyme and variable antigen gene restriction fragment markers. These findings come some years after the observation by Tait5 that the frequency of enzyme electrophoretic variants in a natural population of Trypanosoma brucei conforms to the Hardy-Weinberg equilibrium, suggesting that mating and meiosis occur, and that allele segregation takes place in an orthodox mendelian fashion. Bloodstream T. brucei appear to be diploid6, so if this gene-exchange system is a conventional one meiosis and 'gamete' formation must take place in the vector.

But where in the fly does this clandestine sex occur? The most likely place would be in the salivary glands where the attached epimastigote forms are crowded together under conditions of extreme intimacy; the epimastigote might perhaps furnish gametes, the non-dividing mammal-infective metacyclics derived from them might be zygotes.

The question of trypanosome ploidy will become more confusing with a further publication from groups in Basel and Brussels reporting that Feulgen spectrophotometry gives a metacyclic nuclear DNA content which is half that of the bloodstream form7. The obvious interpretation is that haploid metacyclics give rise to diploid blood infections after mating in the mammalian host. This seems unlikely. Finding a mate would be more difficult in the mammal than in the fly. Furthermore, metacylic-derived clones from heterozygous stocks fail to give rise to homozygous recombinants in blood infections, as they should if metacyclics are haploid, but remain heterozygous*. One possible interpretation of the data presented in this issue, however, is that the hybrids are tetraploid. In order to settle this point their DNA content should now be compared with that of parental stocks.

Clearly, much more work is needed to characterize the new genetic system and the first step should be examination of the progeny from reciprocal back crosses and the generation of an F₂ by mixing different hybrid clones to establish that classical meiosis and recombination occur. So far meiosis appears to be confined to eukaryotes which have conventional mitosis, while trypanosome nuclear division with its non-condensing chromosomes and peculiar spindle apparatus is highly unconventional.

The technique of pulsed-field gradient electrophoresis used for separating small chromosomes has revealed an extraordinarily large number of chromosomes in T. brucei: in addition to several 2,000-kb chromosomes there are about six of intermediate size (200-700 kb) and about 100 minichromosomes (50-100 kb)9. This multitude of chromosomes appears to provide an abundance of telomeres for expression of variable antigen genes. How the countless daughter chromosomes segregate at mitosis is difficult to imagine as electron microscopy shows that the intranuclear mitotic spindle contains only a few microtubules and less than 10 of the structures identified as kinetochores10. Not surprisingly, the intermediate and minichromosomes show considerable variation in size and number between trypanosome stocks and even size variation during successive generations of a

Jenni, L. et al. Nature 322, 173 (1986). Steinert, M. & Pays, E. Br. med. Bull. 41, 149 (1985).

clone. Using existing hybrid progeny it should be possible to examine the inheritance of chromosome variation and of kinetoplast DNA; in the maxicircles of the latter, restriction enzyme polymorphisms have already been identified. so markers are available11

The demonstration of sexuality in Trypanosoma brucei is of importance in the interpretation of epidemiological data. In epidemics of acute sleeping sickness several zymodemes (parasite populations distinguished by their isoenzyme profile) are found in the human population and it now seems possible that such epidemics might arises as a result of genetic exchange between existing zymodemes¹². It will be interesting to see if T. brucei throughout Africa is divided into

reproductively isolated populations. Experimentalists will want to know whether there are restrictions to hybridization; for example, the occurrence of mating types common in other eukaryotes; whether trypanosome sexuality is associated only with late-stage fly infections (most of our knowledge of development in the vector comes from early-stage infections); and whether differences in nuclear DNA content are simply a matter of ploidy or whether gene amplification and chromosome diminution also play a part. Undoubtedly, further surprises are in store

Meteorology

European collaboration on dynamic atmospheric fronts

from K.A. Browning, B.J. Hoskins, P.R. Jonas and A.J. Thorpe

METEOROLOGY is a science that depends on the collaborative links between those involved in developing basic theories and in data collection, analysis and forecasting. The European Mesoscale Frontal Dynamics Project, an intensive programme for observing and modelling active cold fronts passing over north-west Europe, should improve both our understanding of frontal structure and the predictions of the associated mesoscale rainfall distributions. The observational phase of the project is planned for the autumn of 1987, and until then theoretical and modelling work will attempt to define precisely the type and scope of the data to be collected. The project will include university groups, national meteorological offices and research organizations in the United Kingdom, France and the Federal Republic of Germany.

An atmospheric front marks a transition zone between air of markedly different properties, such as temperature or moisture content (see Fig. 1). It is remarkable that air flow should generate such sharp zones, with horizontal scales in the atmosphere of only a few tens of kilometres, rather than maintaining a weaker, broader thermal contrast between equator and pole. In the terms of this definition, frontogenesis — the formation of fronts — is a fundamental fluid dynamical problem. Because rain and snowfall are concentrated at fronts, the problem is of considerable meteorological importance. It is now believed that one of the major challenges in weather forecasting is to predict the variations of precipitation on space and timescales of the order of a hundred kilometres and a few hours that I

are typically associated with fronts in midlatitudes. Such mesoscale variations are intermediate between the 1,000-km scale of depressions and the 10-km and smaller scales of individual convective clouds. Although predictions of the large-scale patterns of depressions and anticyclones are

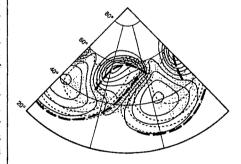

Fig. 1 Model simulation of an atmospheric frontal system¹³. Solid lines, surface pressure contours every 8 mb; dashed lines, low-level temperature contours every 8 K. Areas of strong ascent and descent, respectively, are shown heavily and lightly stippled. Heavy dashed lines, maximum in the low-level vorticity, corresponding to the position of fronts.

now rather accurate even for four days ahead, it is difficult to predict accurately the smaller storms and bands of rain embedded within depressions.

The influential 50-year-old Norwegian model^{1,2} of fronts is now thought to be misleading in several respects: for example, it imagines a depression as forming at a pre-existing frontal discontinuity whereas the modern view is that fronts form after a major depression or cyclone starts to grow. In other words, frontogenesis is now generally thought to follow

cyclogenesis rather than vice versa. But the model still holds in some situations for example, when mature fronts approach the north-east Atlantic, a wave cyclone of scale 200 km can develop on a cold front, producing an intensification of rainfall over north-west Europe. The reasons for the generation of these waves will be investigated by the new project.

There have been several significant advances since the Norwegian model was formulated. First, the westerly flow in mid-latitudes was shown to be unstable, leading to the periodic growth of the familiar depressions or cyclones. This predicts 'quasi-geostrophic' theory' rather accurately the horizontal scale and rate of growth of these systems. Although it suggests that in certain regions of the cyclone the conditions are favourable for the formation of fronts, it predicts that it would take an infinite time to produce the observed near-discontinuity. The formation of a front in a short time interval (of the order of one day) was shown to be caused by a non-linear feedback mechanism at the front', neglected in the quasigeostrophic model. This feedback can be described approximately as follows. As air rises just ahead of the front, its rotation about a vertical axis increases essentially to conserve the fluid dynamical analogue of angular momentum. This increase in rotation forces more low-level convergence and hence more ascent. An assumption of this 'semi-geostrophic' model is that the flow remains in a balanced state; that is, the role of high-frequency motions remains merely one of adjustment of the mass and the wind field to each other.

Where, then, are the essential missing links in present-day understanding of the processes responsible for the formation and structure of fronts? The major factor omitted in the semi-geostrophic model is the role of moisture and the consequent clouds and precipitation. Ideas in the past 5 years concerning the basic structure and dynamics of fronts have led to some insight into the production and organization of frontal rainfall. The main questions still to be answered by the new project concern interactions between the proces-

Corrigendum

In the article 'The class number problem' by Ian Stewart (29 May p. 474) the example of Fermat's theorem that "every prime of the form 6n+1 can be written as x^2+3y^2 for integers x and y" should have read: 31 is such a prime, and 31 $= 2^2 + 3.3^2$.

ses responsible for rainfall and those ultimately determining the development of the front.

Other aspects that will be investigated include the assumption that frontal regions are one of the most active parts of the atmosphere with respect to the exchange of air (and pollutants) between the stratosphere and the troposphere. The tropopause, the base of the stable stratosphere, is typically at a height of about 10 km above the surface, but it becomes highly distorted locally in frontal zones. Such are the vertical circulations at fronts that the tropopause has been observed to descend to within 3 km of the Earth's surface as a narrow 'intrusion'. Within the intrusion relatively dry and stable stratospheric air is brought far down from its normal location, to be mixed into the tropospheric air. The relative position of the intrusion with the surface front is thought to help to determine the degree of development or suppression of the convection that produces localized areas of heavy frontal rainfall. It is possible to track the position of the intrusion by monitoring tracers such as ozone or water vapour, using satellite or aircraft-borne detectors.

An essential hypothesis of semi-geostrophic theory, that of balanced flow, has recently been questioned - see the News and Views article by K. Emanuel', who reported suggestions that frontogenesis is halted if the flow becomes unbalanced, that is, if the operation of the non-linear feedback mechanism leading to the sharp front is prevented by the smaller-scale motion at the front. But recent highresolution observations and modelling work do not seem to support this idea".

A special field programme is needed because the theoretical models cannot be tested using only the data collected by routine weather-observing networks. These observations of temperature, humidity and winds in the upper air have a horizontal resolution of about 300 km, whereas fronts may be characterized by a scale of only 50-100 km. The weather radar networks currently being developed over much of western Europe can provide rainfall data and an indication of the presence of dynamical features over a wide range of scales from hundreds of kilometres down to less than 10 km, but these observations are not sufficient to define the dynamical and thermodynamical structure. Satellite cloud imagery also provides some information on cloud structure down to small scales but it gives limited quantitative information on atmospheric structure (see Fig. 2).

The planned experiment will focus on the western parts of the English Channel. southern England and northwestern France, where fronts approaching from the west (the dominant direction of movement) will be relatively unaffected by lift- l

Fig. 2 Satellite photograph (NOAA-9 visible imagery) of the cloud patterns associated with an atmospheric frontal system broadly res embling that modelled in Fig. 1 (courtesy of The University of Dundee)

ing over hills. It is intended that the conventional upper-air observations over the area of the experiment will be enhanced for short periods centred on the passage of fronts.

Extra observing systems will be used to obtain data over the range of scales required. These systems include specially instrumented aircraft such as a Dormer 128 (ref. 10) operated by German scientists to measure winds and turbulence, and a Hercules aircraft, operated by the UK Meteorological Office, with the capability of ejecting dropsondes that can make frequent measurement profiles of temperature, humidity and wind. Various kinds of ground-based Doppler radar, operated by French scientists", will provide detailed three-dimensional wind fields within areas of rainfall as well as continuous wind profiles within the clear air. Powerful computing facilities will support the running of mesoscale forecast models both in the United Kingdom and France These models are still in their intancy and it is expected that the data sets obtained in the new project will enable their basic hypotheses and predictions to be tested and improved.

Nuclear magnetic resonance

First sight of a single cell

from John Mallard

A PAPER on page 190 of this issue describes the first nuclear magnetic resonance (NMR) images of a single cell. This offers the exciting possibility of fineresolution NMR imaging of cells and collections of cells. The magnetic-field strengths which are used in clinical imaging range from 0.02 to 1 tesla, with about 0.1-0.5 tesla being the norm, but by going to 9.4 tesla and limiting the volume to be studied to a couple of hundred micrometres in thickness, the authors achieve spatial resolutions in the image of the order of 10 to 30 micrometres.

There was much excitement in 1980 when the first clinically useful images of the thorax and abdomen of a patient with multiple cancer deposits were obtained using the technique of NMR imaging^{2,3}. This was the realization of a goal first mooted in the early 1970s (refs 4,5) and bursued in several laboratories since then. By 1984 more than 200 machines were being used in hospitals", with 15 companies manufacturing them.

Nevertheless, I believe that the full potential of this powerful new imaging technique has still to be realized. What is being imaged is the hydrogen protons of water (and fat) in the body, and the parameters which contribute to the formation of contrast in the image are the proton density (or water concentration); the two magnetic resonance relaxation times t_i and t_i ; and the proton movement. The time t_1 is dependent on the interplay of the water molecules and their macromolecular environment, while t_2 is related to the interplay of the water molecules among themselves, and by carefully choosing the sequence, timing and duration of magnetic-field gradients and radio-frequency pulses one can tailor the image to emphasize one or other of these parameters to emphasize one or other aspect of water use in that tissue being imaged.

Because some of the images show vivid anatomical detail of soft tissue, such as the brain, they are immediately compared by radiologists with the images obtained by the X-ray methods, particularly X-ray tomography or X-ray scanning. Naturally, much effort is now being expended in finding which regions of the body and which disease or which abnormality this new imaging technique is better or worse at than these other existing procedures.

Although this exploratory stage is necessary, it is important not to lose sight of the fact that the signals forming the image are from a quite different source than those from X-rays. The X-ray images are formed by differential absorption of

X-rays by the electron clouds of the larger, heavier atoms in the body, whereas these new signals come largely from the nuclei of the hydrogen atoms of the water in the body. The movement of the protons in and out of the imaging volume also influence the signals, and there is now much effort to harness this to show blood flow in major vessels and even to measure the amount of flow, and deviations from it, in these vessels.

No doubt we will now see a rapid exploration of the new NMR instrument described in this issue and a comparison of what it can do with the other micro-

scopic techniques. At first sight this will include the study of material which is alive, and perhaps the really new distinctive feature may be the imaging of the dynamic processes of tissue fluid flow and diffusion. Might not the knowledge gained from the NMR microscope lead us back into attempting to obtain safely a much finer spatial resolution in clinicial images than can be achieved now? Might it also help us to understand the really new contribution of NMR to medicine?

Anoxic oceans and short-term carbon isotope trends

from Wayne D. Goodfellow

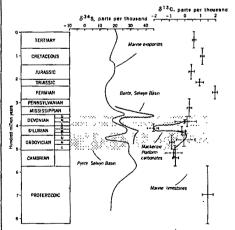

THE relationship between catastrophic geological events, mass mortality of species and sudden shifts in carbon isotope levels was demonstrated for the first time at the Cretaceous-Tertiary mass-extinction boundary, where negative δ¹³C values (see figure legend) were found to be associated with an iridium anomaly¹. Similar relationships between platinoid anomalies and short-term carbon fluctuations have been shown at the Permian-Triassic², Frasnian-Famennian³, Precambrian-Cambrian and, most recently, Proterozoic-Palaeozoic' boundaries. At other stratigraphic boundaries, a shift in carbon isotope values has been observed with no associated metal anomalies6. Many of these changes have been attributed to reductions of the biomass, although other factors may be important.

Changes in carbon isotope values in marine carbonates are influenced by many factors, such the level of mixing of the oceans, fractional preservation of organic matter and biological productivity. Changes in carbon fluxes with time are also important although they are unlikely to explain the relatively short-term and sudden decreases recorded at some System boundaries.

Because living organisms preferentially accumulate carbon-12, an increase of biomass is reflected by a corresponding proportional decrease in the carbon-12 in dissolved carbonate. The converse is also true — a decrease in biological productivity is recorded by an increase in the carbon-12/carbon-13 ratio. Although

there is general agreement that perturbations in productivity can generate changes in carbon isotope ratios in carbonates. the cause(s) of these shifts at a particula. horizon is often unclear.

The recent data of Magaritz et al.5 were obtained from a section from the Siberian Platform spanning the Proterozoic-

Short-term 848 trends in pyrite and barite from the Selwyn Basin and global evaporites in and corresponding curves for δ¹³C charges in carbonates from the Mackenzie Platform and global carbonate11. Small dots, ventilated water column; large dots, water column stratified with anoxic waters.

$$\delta^{13}C = \begin{bmatrix} \frac{^{13}C/^{12}C \text{ sample}}{^{13}C/^{12}C \text{ standard}} - 1 \end{bmatrix} \times 1,000 \text{ parts per thousand}$$

$$\delta^{34}S = \begin{bmatrix} \frac{^{14}S/^{32}S \text{ sample}}{^{34}S/^{32}S \text{ standard}} - 1 \end{bmatrix} \times 1,000 \text{ parts per thousand}$$

Palaeozoic boundary. The $\delta^{\iota 3}C$ values increase 15 m below the Vendian-Tommotian boundary and decrease at the boundary. The authors interpret these changes as a reflection of an initial bloom in biomass followed by a decrease in productivity on the basis of two lines of evidence. First, the association of highly negative δ¹³C values with the Vendian-Tommotian boundary indicates, by analogy with negative isotope shifts observed at other system boundaries, a decrease in productivity; and second, a major phosphogenic episode near the end of the Precambrian is evidence for increased productivity, which perhaps explains the trend to more positive $\delta^{13}C$ values during most of the Vendian.

One of the problems with this approach is that the Precambrian-Cambrian boundary has not yet been defined and the Vendian-Tommotian is just one of several being considered by the boundary committee of the Commission on Stratigraphy. The question of synchroneity with the proposed Precambrian-Cambrian contact (China C marker) of Hsü et al. cannot, therefore, be answered. Without supporting evidence for global catastrophism, such as coincidental anomalies in the platinoid elements, it is impossible to determine whether these isotope shifts reflect local or global processes.

Although the sedimentation rate is poorly constrained, the time span represented by anomalous δ¹³C values is probably large. Magaritz et al. are therefore dealing with relatively long-lived isotope changes that span tens of metres of section compared with the short-term effects that have been measured at mass-extinction boundaries' 4. Any short-term perturbations which exist cannot be resolved because of the large sample spacing.

The problem with the use of phosphate deposits as indicators of a biomass bloom is that most of these deposits are poorly constrained in time, making correlations with boundary events difficult. Furthermore, the lack of a clear relationship between trends of short-term changes in carbon isotopes and phosphogenic episodes indicates that phosphate deposits do not reflect, at least on a global scale, periods of increased productivity. But major phosphate deposits do occur at the onset of episodes of vertical mixing after periods of oceanic stability7, which suggests that other factors, such as the ventilation of anoxic oceans, influenced the isotope composition of dissolved carbonate.

During the history of the Earth, the oceans were not always as well mixed or ventilated as they are today. Major periods during which the oceans were stratified with an upper oxygenated and lower anoxic water column have been identified for the Mesozoic^b and Palaeozoic9. Carbonates precipitated from the lower anoxic water column are enriched

from Nature 34, 249; 15 July 1886 100 years ago Captain Ericsson's Pyrheliometer

in ¹²C because of the oxidation of organic matter by sulphate-reducing bacteria, as shown by the simplified reaction:

$$2CH,O + SO_4^{3-} \rightarrow H,S + 2HCO_5^{3-}$$

Because the amount of carbonate generated by this process is directly proportional to the fraction of sulphate reduced to sulphide, and as this fraction controls the δ^uS value (see figure legend) in the product sulphide, & S values in pyrite provide a measure of the amount of organic carbon oxidized in anoxic basins. As shown in the figure for the Palaeozoic Selwyn Basin of northwestern Canada, δ⁴S values increase during periods of ocean stratification until they approach or exceed those for coeval sulphate precipitated from the upper ventilated water column^{9,10}. Carbonates precipitated from the anoxic water column have δ¹³C values as low as -10 parts per thousand.

On the adjacent Mackenzie Platform, carbonates deposited from the upper water column during the Ordovician and Silurian display δ¹¹C values more positive than those for average carbonates" (see figure). The ventilation of the oceans, by contrast, should result in a shift to more negative δ^{13} C values caused by the mixing of isotopically light carbon from the anoxic water column with surface waters. This relationship is illustrated for the Mackenzie Platform by a deflection to more negative values in carbonates of the late Silurian (see figure).

The similarity of short-term carbon isotope trends in carbonates from the Mackenzie and Siberian platforms, both in the magnitude of the isotope shifts and in the polarity, indicates that biomass is not the only factor that influenced isotope ratios across the Vendian Tommotian boundary. This is particularly true to: stratigraphic horizons where synchroneity of events cannot be determined and where there is no supporting evidence for global catastrophism. More isotope and geochemical studies of carefully controlled sections sampled in detail across event boundaries are needed -- only then will the processes controlling the tractionation of carbon isotopes be fully understood

Palaeoecology

Surface water acidification

from Hans M. Seip

Few topics have been the subject of so much recent debate as acid precipitation. Are there other causes for the surface water acidification and the dramatic loss of fish populations observed particularly in Scandinavia, but also in other parts of Europe and in North America? Palaeoecological studies, such as the one described on page 157 of this issue', support deposition of compounds of anthropogenic origin as the primary cause.

It is now generally accepted that the recent increase in acidity (H+ concentration) of precipitation is caused by anthropogenic emissions of sulphur and nitrogen oxides. Recent surface-water acidification is also well documented. Although there is a reasonably good correlation in space and time between acid precipitation and water acidification, it is difficult to prove a causal relationship.

The main alternative hypothesis was originally forwarded by Rosenqvist2, who believes that soil acidification caused by changes in land use is the most important cause of the recent water acidification. Although this view is not generally accepted, it has some support3 and there is a consensus on which processes to consider; the differences arise in their relative importance.

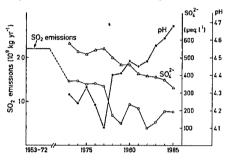

Because most of the precipitation will come into close contact with the terrestrial part of most catchments, acid soil is a prerequisite for acid water. Changes in the chemical properties of the soil, as well as changes in the hydrology5, affect the water chemistry. Several studies demonstrate soil acidification in Scandinavia and in Central Europe, which at least partly seems to be caused by acid deposition. Except for agricultural areas, estimation of H⁺ fluxes to the soils supports the importance of acid deposition in acidification.

Water acidification depends not only on soil properties, but also critically on the concentration of 'mobile' anions, particularly sulphate, nitrate and chloride, that move easily through the terrestrial part of the system. Because a charge balance must exist in any solution, increased anion concentration will lead to increased cation concentration, including increases in H+ and aluminium in runoff from acid soils. In most areas, the most important mobile anion seems to be sulphate; nitrate is mainly taken up by the vegetation but may affect water acidity, particularly during snow melt.

It is difficult to quantify the relative importance of acid deposition and other causes of water acidification. Simulation models indicate that increased sulphur | the diatom record. Despite some uncer-

deposition may cause a considerable decrease in the pH of surface water while deposition may cause similar increases^{6,7}. These theoretical calculations are supported by observations around Sudbury (see figure), where the emissions have been dramatically reduced since 1972 and surface water quality is improving. Conversely, a historical approach used in three Norwegian studies did not reveal a relationship between land-use changes and loss of fish populations8.

Jones et al. combine a detailed palaeoecological study of vegetation changes from the last glaciation until the present day around a lake in Galloway, Scotland,

The decreasing emissions at Sudbury, Ontario, have resulted in decreasing sulphate concentrations and acidity in the Clearwater lake 14.

with estimates of historical pH values using the diatoms in the lake sediments. Despite the rather dramatic changes in vegetation from a forest to an acid peatland, the pH of the lake remained surprisingly stable between 5.4 and 6.0 until the recent acidification started in about 1850. Although this study considers vegetation changes in particular detail, other palaeoecological results support the conclusion that acid deposition is a necessary condition for the recent acidification 9-12. For example, the pH of a lake in the Adirondack Mountains, United States, was about 5.7 during the period 1800-1950 despite major logging operations in the catchment. From about 1950 the inferred pH dropped to about 4.7 (ref. 12).

How reliable are these results? One complication is that the distribution of diatoms depends not only on pH, but also on other factors, such as the concentrations of humic substances and major ions in the water. The dependence on the content of humic substances has been used to infer changes from moderately acid humic water to more acid clear water in two Norwegian lakes, presumably because of acid deposition¹³. Seasonal variations in water acidity are often important and it is not clear how acid episodes are reflected in tainties in interpretation, palaeoecological methods may be the best way to determine the importance of acid deposition.

Can we draw the general conclusion that water acidification does not occur in an area without acid deposition? The diatom studies usually give inferred pH values of more than 5 in pre-industrial times for lakes that are now acidified. This agrees with the observation that fresh water in 'clean' areas seldom has a pH less than 5.0. There are simply not enough anions to balance the charge of high concentrations of H+ and aluminium ions. There are exceptions — highly coloured water may contain enough organic anions to make it more acid. But the recent acidification is not caused by increased concentration of organic compounds.

Sea-spray deposition with high concentrations of Cl and Na+ may also cause acidification if sodium is retained and H+ ions are released from the soil. But in a stable terrestrial system there will be no long-term accumulation of Na* and therefore only episodic acidification from sea-spray; in an aggrading system sodium may accumulate for longer periods.

Afforestation causes important changes in hydrology and soils, and several studies in the United Kingdom show more acid and aluminium-rich waters in afforested compared with non-forested areas in exposed regions. It is not clear whether a similar acidification would occur in areas with natural precipitation. The forest 'filters' the air and thus increases the deposition of both anthropogenic and natural compounds. Increased sulphate concentration in runoff may therefore be the main cause of acidification here.

In conclusion, there is at present little solid evidence for recent water acidification in areas not exposed to acid deposition. If occurring, it is likely to be found in areas with high sea-salt influence and recent vegetation changes such as afforestation, but the primary cause is evidently anthropogenic emissions of sulphur compounds.

SCIENTIFIC CORRESPONDENCE

Human gene cloning: the storm before the lull?

SIR-Hardly a week goes by without an article in Nature describing the cloning of a human DNA sequence. Yet it is barely nine years since the first cloning of a human gene sequence, chorionic somatomammotropin, was reported in Nature¹. Since then, some five hundred different human gene sequences plus many anonymous DNA segments, have been reported in a total of nearly 2,500 independent published articles2 (as evidenced in Gene Communications, a quarterly updated newsletter obtainable from the authors on request). Such an exponential increase in knowledge accumulation is by no means unique. Examples of this phenomenon have included the literature explosions associated with cyclic AMP after the introduction of the second messenger hypothesis in 1958² and the discovery and analysis of hereditary amino acidopathies after the advent of chromatographic methods'.

We calculate that were the present growth in the number of reports of cloned genes to be maintained, their number would overtake the total number of biological publications in 1992 and that of all scientific publications by 1994 (Fig. 1), still leaving the majority of the human genome untouched. However, this year the first signs of a plateau are becoming evident. It is interesting to speculate upon the various factors which might affect publication rates over the next few years.

A slow-down factor could be the finite size of the human genome (3×10^9) base pairs) — although the number of gene sequences which it contains, perhaps in excess of 100,000, is sufficiently large to ensure that there is a long way to go before any law of diminishing returns begins to operate. But given its limited and already stretched resources, the scientific community will sooner or later have to decide whether it can afford the not inconsiderable redundancy so characteristic of research efforts in this area.

This redundancy of effort is apparent from the number of independent reports of the cloning of certain human DNA sequences. For example, the cloning of adenosine deaminase and of T-cell receptor α and β chain cDNAs have each been achieved eight times. There are 17 separate reports of a cloned c-mvc genomic sequence and 33 independent reports of the cloning of the β -globin gene, although, in fairness, some of these are mutant alleles. While a certain degree of competition is to be expected and indeed welcomed in science, redundancy on this scale clearly calls for some more effective means of coordinating research efforts at the international level. It is, however, to be expected that no such let-up is likely in the hunt for those gene sequences deemed worthy of commercial exploitation. Presumably, strong competition will still characterize the drive to clone genes coding for proteins of economic and/or medical importance. Furthermore, an ever increasing number of laboratories are involving themselves directly or indirectly with cloning and mapping the human genome. The synthesis of molecular biology and human genetics seems able to attract an increasing number of adherents. How long the cloning fashion will be able to lure young researchers remains an open question, but for most laboratories, cloning is not an end in itself, but a means to an end, for example, functional analysis, spawning further booms in clone analysis.

One further factor which will affect publication rates is the future editorial policy of the eighty or so journals that at present publish these reports. Although to some extent offset by the likely future increase in journal numbers, the number of published cloning reports should tend to decline as a result of a probably tightening-up of standards and criteria for article acceptability. It is anticipated that authors will be expected to report on a larger number of sequences, a more complete sequence or to have undertaken in-depth structural or functional studies. Cloning data may in the forseeable future have to be relegated to an information repository in the form of an electronic data base, a development which will be accelerated by

novel, more effective cloning, genome walking and sequencing strategies. It remains to be seen whether the level of acceptance of such novel means of data storage and transfer is sufficient for any appreciable effect to become apparent in the near future. Perhaps the rate of human gene cloning

may even decline because people are simply getting bored with it. But it is also true that man's feeling of self-importance will probably not be satisfied until the last bit of his genome has been sequenced and filed somewhere.

Immunotoxins to combat AIDS

SIR—Of the three therapeutic approaches to acquired immune deficiency syndrome (AIDS) suggested by Klatzmann and Montagnier¹, Singer and Shearer have highlighted the possibility of attenuation of the CD4⁺ cells, which are the host for the virus associated with AIDS (HTLV-III/LAV), by infusing monoclonal anti-CD4 or anti-class II HLA reagents.

A more reasonable approach, we suggest, would be to use immunotoxins' conjugates of a specific antibody and a plant or bacterial toxin — directed specifically to the CD4 cells. The toxic moiety is a ribosome inactivating protein (RIP), either a single A chain or both an A chain and a B chain (which is a monovalent lectin). Immunotoxins containing A-chain RIPs have a definite advantage over the two-chain RIPs as they can be made absolutely target specific'. There is now good evidence that only one molecule of the enzymatic, toxic A chain entering the cytoplasm of a cell is sufficient to bring about the cell's destruction by totally inactivating its protein-synthesizing machinery⁵. Immunotoxins offer the advantage of providing both specificity of targeting through the antibody moiety and extremely effective inhibition of messenger RNA translation (which is increased by orders of magnitude by the product of the tat-III gene of HTLV-III/LAV in infected cells') by virtue of the toxophore moiety.

By subverting the stratagem used by the virus for its replication, the administration

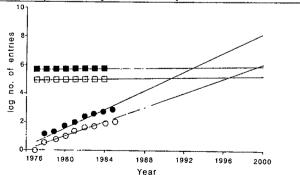

Fig.1 Exponential growth of publications per annum on cloned human DNA sequences: all reports (filled circles) and first reports on protein coding sequences (open circles). For comparison the number of publications covered by Biological Abstracts (open squares) and Science Citation Index (filled squares) are given.

of immunotoxins would greatly diminish the number of virus particles released, over a period of time, into the circulation following the destruction of CD4⁺ cells. As a consequence of this reduced number of viral particles thus released, they could probably be neutralized effectively by the antibodies already present in the patient's blood. On the other hand, infusion of anti-CD4 antibody alone (which by itself cannot attenuate the viral population) would release far greater numbers of viral particles. As a result, the neutralizing capacity of the circulating antibodies may be considerably reduced. The injection of antiviral antibodies to neutralize the virus would then be required. Because of the antigenic drift8 noted with this virus, extraneous infusion of anti-HTLV-III/LAV antibodies may not be particularly helpful in neutralizing the large pool of HTLV-III/LAV released by treatment with anti-CD4 antibodies.

Thus the administration of immunotoxins in miniscule amounts (as RIPs act in a catalytic manner) might forestall the spread of AIDS virus. Moreover, as only a small proportion of CD4+ cells are infected by the virus and as fresh peripheral blood lymphocytes of AIDS patients do not show the presence of viral DNA, there will probably be no necessity for immuneenhancing therapy with immunotoxins.

Earthquake prediction and electric signals

SIR-In a comment in News and Views' P.W. Burton discussed our publications in Tectonophysics² on the prediction of the epicentre and the magnitude of earthquakes within a time window of 7 to 115 hours, based on the monitoring of the simultaneous changes of the electric field of the Earth observed at a number of sites. Burton expressed doubts about the claimed connections between earthquakes and the precursor signals, especially during periods of high seismicity. Of course, there is a high probability of an earthquake occurring somewhere within, the time window, but we have isolated a large number of events in both time and seismic region.

A recent case, with an exceedingly small probability of having been predicted by chance, illustrates our point. On 17

December 1985, we presented a prediction to the session of the Greek Special Committee on Earthquake Prediction, which was recently established by the Greek Ministry of Public Works and consists of geologists, seismologists and physicists. The electric signals allowed two solutions, one for an event of magnitude 4.8 in the sea to the south of Kalamata (southern continental Greece) and the other for a 5.2 mag event on the coast of Asia Minor near the island of Samos. Forty hours later a 5.2 mag event occurred within 150 km of the site expected from the second solution. As no earthquake with M > 4.7 had occurred within the 75,000-km² area 36.7-40.0 °N and 25.0-27.5°E for at least the previous 14 months. the time-probability is smaller than 10⁻². Obviously the probability of simultaneously predicting the time, epicentre and magnitude is appreciably smaller.

Another recent case is the following: On 29 March 1986 a 6.1 mag event occurred at 38.3°N-25.3°E. Four days earlier the government had been officially informed of an impending 6.1 mag earthquake. The error in the prediction of the epicentre was less than 50 km.

The stability of zoological nomenclature

Sir-As one of those cast by Erzinclioglu and Unwin (Nature 320, 687; 1986) as "having a legalistic turn of mind", I would like to protest the spirit, as well as the content, of their letter which was intended to detail the inadequacies of the International Code of Zoological Nomenclature and to protest the "tyranny of the Commission".

First, the writers do not seem to understand the meaning of stability in the sense of the code. Stability has never been taken to mean that a name shall remain unchanged and unchangeable: the preamble of the Code states that, "All its [Code] provisions and recommendations are subservient to these ends [promoting stability and universality in the scientific names of animals] and none restricts the freedom of taxonomic thought or action." Further, the plenary powers of the Commission, defined in Article 79, outline the responsibility of the body to maintain stability and specifically refer to the suppression of a senior homonym as a potential option in assuring stability.

With regard to a few specific points raised by Erzinclioglu and Unwin, the

Code has, for several editions, made a clear distinction between the endings of names and the name of the taxon. Thus, changing the ending of a species name to agree with that of the genus in no way constitutes a change of names.

A similar observation, of course, applies to the authors' argument regarding elevation of subfamily groups to the family level. The reasoning behind the rules governing change of rank within the family-group seems altogether clear and I cannot imagine such a change could cause confusion

In their lengthy summary of the change of species names for the medically important African fly Auchmeromyia luteola, or perhaps I should say A. senegalensis, the writers do not seem to be offended by the change in generic placement, which presumably occurred before their entry into the world of nomenclature, but only by the discovery of an obscure senior homonym and subsequent name replacement. Their irritation is misplaced and might better have been directed at the author(s) of Catalogue of the Diptera, who chose to offer a replacement name rather than to maintain the well-known name and refer the matter to the Commission. This option has existed for years and is the rational way to resolve this kind of problem and assure stability.

Erzinclioglu and Unwin seem particularly confused regarding the relationship between the rules of nomenclature and the classification of organisms. Adherence to the principles of cladism or, for that matter, "traditional" systematics have no bearing whatsoever on the value of the Code.

Finally, those of us who "mindlessly" adhere to the Code resent the notion that anarchy is the only sane alternative to felt weaknesses in the rules. There is, and always has been, the alternative of petition for change in the document. In my opinion the present Code constitutes an improvement, in some areas, over the previous edition. There remain very real problems regarding application of the rules to collective groups and ichnotaxa — problems that will probably never be resolved to everyone's satisfaction — but there is a mechanism within the rules to allow change to be proposed.

I find it ludicrous to consider the Commission as a group of hooded tyrants whose purpose it is to impose their arbitrary will upon the scientific community, from which, of course, they were elected. It may come as some consolation to Erzinclioglu and Unwin to note that by the act of expressing their interest in nomenclature, they have qualified themselves for nomination to election to the Commission.

RODNEY M. FELDMANN

The path to solid success

R.V. Jones

A Life in Science. By Sir Nevill Mott. Taylor & Francis: 1986. Pp. 198. £15, \$30.

Nevill Mott's concise autobiography shows how fortunate he was in his parents. They had both been research students at Cambridge under J.J. Thomson, and throughout their lives he could share with them his professional experiences in a happy manner rarely granted to a physicist. They could thus take informed pleasure in his first success in research, the prediction in 1929 — on the basis of the new quantum mechanics — of the way in which α-particles would be scattered by helium nuclei.

They could also enjoy pen-pictures of life in Copenhagen with Niels Bohr, in Göttingen in the earliest days of quantum mechanics, and back in Cambridge with Rutherford and Dirac. Writing of his Cambridge and Copenhagen periods, Mott twice uses the phrase "sink or swim" to describe the then prevailing atmosphere in which research students were expected to fend for themselves. This will ring true to those of us who entered physics before 1939.

His time as a student ended in 1929 with appointment to a lectureship with W.L. Bragg in Manchester. He held this for only a year, before an invitation from A.M. Tyndall took him to Bristol as professor of theoretical physics at the age of 28. Protected from administration by Tyndall, one of the wisest of laboratory heads, Mott pursued his developing interests in solid state physics; and over the next dozen years he became senior author of three notable books, "Mott and Massey" Theory of Atomic Collisions, "Mott and Jones" Theory and Properties of Metals and Alloys and "Mott and Gurney" Electronic Processes in Ionic Crystals. He was only 31 when elected to the Royal Society — "Nowhere near a record", he tells us, for "Paul Dirac was elected when he was 28".

The Second World War brought Mott into contact with the Army, first at Anti-Aircraft Command, then at the Army Operational Research Group at Petersham and finally at Fort Halstead as Superintendent of Mathematical Research in Armaments. Those who knew him before 1939 were struck by the way the war brought him out of his shell. As for many of us, he was now working with soldiers and grappling with practical problems of the utmost importance. I remember his contribution to the construction of reflecting screens of chicken wire for radar aerials: if a particular mesh would let 10 per cent of the energy leak backwards, then halving the pitch of the mesh would roughly halve the leakage: but if instead of using extra wire in the closer mesh, the same amount were woven into a second screen placed behind the first, then each screen would only let through 10 per cent of the radiation incident upon it, and so the double screen would let through only one per cent. But while Robert Watson-Watt could well have appreciated the elegance of this idea, I cannot imagine him being so happy with Mott's giving the credit, as he does, to Edward Appleton for the use of pulse methods in radar.

The experience at AA Command gave Mott "a deep respect for the professional soldier". At the same time the war led him to realize the importance of industry to Britain, and the benefits that could ensue

taken not by him but by the body of fellows. Tizard had experienced the same thing at Magdalen in Oxford where, as the Dictionary of National Biography records, he found it difficult "to pilot controversial issues through a very varied and independent-minded body of fellows". "Looking back", Mott writes, "on both my election and my resignation, it seems like one of Snow's novels; we used to say that Snow 'didn't know the half of it".

When he resigned from Caius in 1966 Mott still had another five years in the Cavendish chair, where he devoted much effort to teaching, both in the university and in schools. He chaired the physics committee of the Nuffield Scheme, where the main idea was "learning by doing". But, he writes,

I would have hated to do it this way. To me the laws of physics are to be approached through mathematics, and their validity and beauty become clear when expressed in mathematical form. My hero was Clerk Maxwell rather than Faraday....

He also had reservations, although he did his best for the scheme, over the Treve-

Nobel quintet— (left to right) Philip W. Anderson, W.H. Brattain, Nevill Mott, John Bardeen and J.H. Van Vleck. Anderson, Mott and Van Vleck were joint Laureates in 1977, and Brattain and Bardeen (with William Shockley) in 1956. Bardeen was again a winner in 1972, with Leon Cooper and J. Robert Schrieffer.

if university science were more closely linked to it. This was one factor that led him to return to Bristol rather than accept a chair he was offered in Cambridge.

The post-war years in Bristol scintillated with success. Mott succeeded Tyndall as head in 1948, and was surrounded by a galaxy of talent that included C.F. Powell, C.R. Burch, P.H. Fowler, F.C. Frank and J.W. Mitchell. But when, in an act of self-sacrifice, W.L. Bragg left the Cavendish chair in 1953 to restore the fortunes of the Royal Institution, Mott accepted appointment as his successor—just too late for his mother to be told of this "overwhelming honour".

In 1959 Mott also became Master of Caius College, Cambridge: surprisingly, it had become fairly common in Cambridge for an individual to be head of a college, as well as of a large laboratory. Mott found the two jobs very different. In the laboratory, after listening to opinions, he took the key decisions himself: in college he was expected to abide by decisions

lyan scholarships initiated by Kurt Hahn: "It was dangerously near 'character rather than intellect' which was of course anathema to me". He was happiest with his chairmanship of the Royal Society's education committee, writing a report in 1979 on the needs of talented children. The report concluded "that mixed ability teaching could be successful only with exceptionally able teachers"; instead "our working party believed that as far as possible talented children should advance at their own pace, and with this in view favoured 'setting' in science and mathematics from 13 years onwards".

Relinquishing the mastership of Caius gave Mott more time for research, and his interest was aroused by the properties of non-crystalline semi-conductors. His contributions to the theory, which have continued after his retirement from the Cavendish in 1971 to the present day, were recognized by the award of a Nobel Prize in 1977. So while advances in theoretical physics are nearly always made by

young men, Mott's best-rewarded work has been done, most remarkably, in retirement — an exemplary encouragement to us all.

As for his method of creative reasoning. some clue may be gained from Smoluchowski's retrospective comment on the early days of solid state physics: "Mott... and his colleagues horrified us by their 'simple' visualizable and seemingly uncomplicated models and mathematics". So, with his models such as "swollen atoms", Mott is in a tradition expressed by H.G.J. Moseley in 1914: "the French point of view is essentially different from the English. Where we try to find models and analogies, they are quite content with laws". By his practice, then, Mott has a foot in one camp, and by his professed predilection for laws, also a foot in the other. Bestriding both, his is one of the most sustained lives of success in physics, recognized by numerous medals and 27 honorary doctorates.

A Life in Science is written with great economy, throwing laconic sidelights on many issues into which Mott's pursuit of science has drawn him. "Kindness with firmness" is a pervading trait, the former being exemplified in his remark that "The greatest pleasure in life is putting others on the way to success", the latter in stopping the project for a linear accelerator in Cambridge in one of his first acts as Cavendish professor.

In the deepening attention that many in science are giving to religion, Mott's own personal statements on the matter will be appreciated. In 1929 he wrote to his fiancée, "If you wanted to become a Roman Catholic, I should want to die. The trouble is that I can't think about the institution because it fills me with absolute physical disgust...". While this pristine view has been much mellowed by age and by an appreciation of the services performed by many devoted Catholics, "something of my antagonism remains". But Mott feels no such antagonism for the Anglican Church: indeed in retirement he has been baptized and confirmed as a member, and he devotes a whole chapter of the book to religion. He regularly attends church

finding it helpful to worship God in company with other people. If some things that are repeated in the Creed do not correspond with what I believe, such as 'born of the Virgin Mary', I accept what is said because to me the Christian religion is the sum of the beliefs of Christians throughout the ages, not only those of our present generation.

Each man's religion is a matter for himself, and we can only be grateful to one who has spent a long life so eminently in science for exposing so frankly his personal conviction.

Getting the picture to tell the story

P.W. Hawkes

Image Analysis: Principles & Practice. Joyce-Loebl:1986. Pp.250. Pbk £35, \$50. *

THERE are four grand themes of digital image processing: acquisition and coding; enhancement; restoration; and analysis, including pattern recognition. This last activity differs from the others in that the result is not a better image or one that is transformed in some way, but information about its contents. The information often comes in the form of a histogram or tables of data. In a karyogram, for example, the properties of the various chromosomes present might be listed; in quality control in a manufacturing process, certain dimensions might be monitored and the process interrupted if these exceeded preset limits; in aerial cartography, areas of forest and field, river and lake, factories and dwellings might be recognized, measured and their relative separations characterized in some way.

There have been many books on image analysis but none quite like this one — in

* Available from Rosalyn Kell, Joyce-Loebl, Marquisway, Team Valley, Gateshead, Tyne & Wear NE11 OQW, UK, or Bill Burnip, Joyce-Loebl, c/o Nikon Inc., 623 Stewart Avenue, Garden City, New York 11530, USA.

simple language, and with ample illustration, it enables the reader to use a commercial image analyser to the best advantage. The coverage is broad but is not correspondingly shallow, though the mathematical foundations of the various operations are rarely described. The text covers acquisition and digitization, but it will be used principally for its chapters on image processing, detection and measurement techniques. These introduce the reader to the ways of locating specific structures, of amending images by erosion or dilation (sic), of identifying and coding boundaries, and of characterizing shape, among many related topics. Subsequent chapters deal with colour images, computing (almost too brief to be useful) and a number of case studies. Each chapter ends with a bold-face summary; these read \r more like collections of great thoughts than scientific abstracts: "classification is a useful technique, but can become complex if many different kinds of measurements are used" gives an idea of their profundity.

Excusably, the anonymous authors had the Joyce-Loebl analyser in mind, but the book is not unduly partisan and gives an exceedingly clear and easily assimilated account of a great deal of disparate material. There is no better book for anyone involved with these machines who would be daunted by a more mathematical account.

Disordered thoughts

P.W. Atkins

The Unfinished Universe. By Louise B. Young. Simon & Schuster: 1986. Pp.239. \$17.95.

THE argument of this book is that a great creative process is taking place within the Universe, with us as witnesses and participants, and that matter has an innate tendency to achieve greater complexity. Form is emerging like a butterfly from a chrysalis, and the process that began when quarks coalesced into protons is now moving towards its culmination. The argument depends on a specific rejection of the view that the Universe is running down into a state of disorder.

The case in favour of this formative tendency is passionately argued, and it is plain from the style of the exposition that Mrs Young is deeply in love with the world and with her vision of science, and longs to share her wonder and awe. Such books should be approached with a special cast of mind, for it is important not to allow the style to obscure the content. This is espe-

cially true of one wrapped in a jacket bearing messages from three highly respected scientists, one of whom claims that the book releases us from the stifling imprisonment of the Second Law of thermodynamics, another that Mrs Young's view that a creative process is taking place "is an idea... of great importance" and a third who finds it a strangely beautiful guide.

I feel outnumbered, for I find it none of these things. Passion there certainly is, and I can see why some might find the prose "lovely". I will disregard the little slips that don't matter very much (such as ascribing seven electrons to chlorine and the heat of the Earth to thermonuclear reactions in its core). I will also largely ignore (but it set my antennae waving) the author's rejection of the concept of force and its replacement by some kind of vague, non-quantified, tendency of particles to congregate into more complex form (p.41). I will concentrate instead on the central idea, that the Second Law cannot fully account for the phenomena of the world, and particularly for the phenomenon of life. Mrs Young admits (p.120) that the trend postulated by the Second Law is the opposite of the one she proposes, and therefore her thesis depends on her ability to demonstrate the Law's invalidity and incompleteness.

I can see why Mrs Young thinks it inadequate: it is because she appears not to have understood it. Chapter 6 is a travesty of thermodynamics. In the first place, a waterfall (p.119) is an excellent example of a process on which, as expressed, the Law is silent. Secondly, when the Law is first presented (p.119) it is stated in terms of the tendency of the entropy of a system to increase, without it being emphasized that the system must be isolated. A partial recovery is made three pages later when Mrs Young reminds us that physicists have "explained" (her quotation marks) the apparent spontaneous local emergence of order by insisting that the Second Law refers to a totally closed (by which she should mean isolated) system. However, she rejects this "explanation" by remarking (p.123) that it is not possible to ascribe numerical values to "the different levels of complexity" of a system, which I take to be the denial of the view that the entropy change in a system can be expressed quantitatively. That of course is silly: huge tables of thermodynamic data exist and other data can result from well-defined experiments. One of the main objects of statistical thermodynamics is to do this very calcu-

Slippery language erects false tests. In what should be a technical account of entropy and its calculation, the author asks (p.124) "how can we place a value on the creation of the first living thing?" as a paraphrase of "what is the change of entropy of the system?". Moreover, in a book on the application of thermodynamics to life, surely one should expect to find a discussion of the behaviour of open systems, dissipative structures and entropy production in states far from equilibrium?

Far from being a release from the stifling imprisonment of the Second Law, the book is an essay based on misunderstanding. Far from being a strangely beautiful guide it is a snare for those with a passion to know but not the ability to judge. Far from being important enough to be published and await its time (p.227), the central thesis is nonsense. I am sorry to be so harsh, for I can sympathize with the author's passion.

Down to physicists

Peter J. Smith

Continuum Theories in Solid Earth Physics. Edited by R. Teisseyre. *Elsevier:1986. Pp.566. Dfl. 290, \$107.50.*

THE American geologist M. King Hubbert was wont to startle his audiences with the proposition that as science advances it becomes not more complex but simpler. This is, of course, one of those intellectual teases that is both true and false but more false than true. What King Hubbert had in mind was the plethora of apparently disparate observations and unrelated hypotheses which, once plate tectonics had been discovered, could be summarized as a paradigm in half a page. He had a nice philosophical point, but one that ignores the fact that working Earth scientists are not primarily philosophers. Students and researchers, forced to look behind the simplifying mega-patterns of the Earth, are all too aware not only of the increasing complexity but also of the growing burden of knowledge represented by ever more detailed observations, hypotheses and interpretations.

There is, moreover, a quite different sense in which King Hubbert's dictum is suspect. His exemplifier, plate tectonics, is essentially a theory of what happens rather than of how or why. It has been clear for some time now that the latter questions can only be addressed in terms of the solid-state physics of the Earth's interior, a development that raises complexity to bewildering heights for those versed only in conventional geological methods. Continuum Theories in Solid Earth Physics, which originated in Poland, proves the point with a vengeance. About 80 per cent mathematical and requiring a good working knowledge of tensor analysis applied to continuous media, the book demonstrates just how "non-geological" the fundamental problems of Earth behaviour really are.

The topics on the agenda here are the theory of Somigliana dislocations and its application to earthquake mechanics and aseismic creep; fracture theory and its relevance to seismology; the mechanics of continuous media with special reference to seismology; the behaviour of porous media; the theory of thermal stress in the Earth's interior; thermal convection; the nature of electromechanical and magnetomechanical coupling; and magnetohydrodynamic processes in the Earth's core as the source of the geomagnetic field. In each case, although the emphasis is on mathematical development, due attention is paid to the need to relate theory to the results of observation and experiment (not always a feature of books of this kind) and for the most part there is sufficient |

description to enable the non-mathematically inclined to get at least the gist of what is going on. It is interesting, too, to note that the Poles are far more familiar with what goes on in the West (and Japan) than are Western scientists with developments in Poland. As a result, there is little evidence here of a "Polish view" of Farth physics and thus, in contrast to many treatises emanating from the Soviet Union, no false impression of the subject having originated and developed quite separately in the East.

Whilst this commendable internationalism gives point to the publication of the book in Poland, it is less easy to see the merit in making a somewhat coals-to-Newcastle translation into English. The very lack of parochialism has the ironic consequence that there is little, if anything, here to be learned by Western Earth scientists. Nor, even if there were no comparable texts already in the West. would the volume be a suitable text for the uninitiated. As D.L. Turcotte and G Schubert so ably showed in Geodynamics: Applications of Continuum Physics to Geological Problems (Wiley, 1982), it is perfectly possible to teach Earth physics without tensors and get through to a wider audience into the bargain.

Tema 5 – Proceedings of the 5th International Symposium on Trace Elements in Man and Animals

edited by C.F.Mills if Bromner and J.K.Chesters

Accounts of recent studies of the biological role of the essential trace elements of the biochemical and pathological effects of defects, or excess, and of the significance of such problems in human and animal is different presented. This volume includes reports both of the scientific discussions that followed presentation of marity of these papers and of workshop so is root that considered problems associated with the detection of trace elemint related disorders.

Tema 5 will be of great interest to research workers on trace elements ar well as lecturers inutritionalist , pathologists and veterinarian .

How important is natural selection?

J.S. Jones

Natural Selection in the Wild. By John A. Endler. Princeton University Press:1986. Pp.336. Hbk \$40, £26.65; pbk \$13.95, £9.30.

THE most influential evolutionary book of the past ten years is, without doubt, Motoo Kimura's Neutral Theory of Molecular Evolution, and of the decade before that R.C. Lewontin's The Genetic Basis of Evolutionary Change. Lewontin pointed out the difficulties of explaining molecular polymorphism using traditional models of natural selection acting at single loci, while Kimura argued cogently that the most important force in controlling the evolutionary fate of most newly arising mutations is not selection but random genetic drift. This relegation of natural selection to the role of evolution's policeman, who acts mainly to remove alleles deviating from an acceptable norm and ignores the vast majority of genes in populations, is now central to large parts of theoretical population genetics, to molecular evolution and to the reconstruction of phylogenies. John Endler's impressive book attempts to restore natural selection to its traditional place as the driving force of evolution. It may become an evolutionary classic of the next decade.

As Endler points out, the term "natural selection" has meant very different things to different people. After wandering briefly in the philosophical fog which is thicker in evolutionary biology than in any science apart from psychology, he produces a definition of selection close to the Darwinian one - variation, inheritance and genetic differences in the chances of reproduction — or even to that of Oscar Wilde, that "nothing succeeds like excess". Natural selection does not necessarily lead to evolution, and it includes many biological processes apart from differential mortality. Indeed, a survey of experiments on selection in nature suggests that inherited differences in survival are less important than are those associated with mating ability, fertility or fecundity.

There have been numerous attempts to measure selection in the wild. Many of these have failed because of poor experimental design, and Endler suggests a number of ways in which selection might acceptably be demonstrated in natural populations. He discusses ten kinds of information that can identify selection, from simple correlations of gene frequency with environment, to comparisons of the same genes in related species, and

to demographic studies and experimental perturbation of populations in nature. The road to detecting selection has many pitfalls. Endler finds 25 reasons why we might fail to detect it when it does exist but, comfortingly, only 21 ways in which selection might be identified when in fact it is not operating. His extensive analysis of work on natural selection in the wild suggests that strong selection on morphological characters and polymorphic alleles -selection of the intensity used by animal and plant breeders — is commonplace in nature, and that the general assumption that differences in fitness of more than about 10 per cent are rare is simply incorrect. It is nevertheless rather depressing to learn that there is as yet no case in which natural selection acting over an organism's whole lifetime has been measured. It is also true that if size and shape are controlled by many genes of individually small effect, then strong selection on morphological characters may still allow genetic drift to determine the evolutionary fate of most mutations at such loci. This distinction between natural selection on the phenotype and the genotype may yet bridge the gap between those who emphasize the importance of random change in evolution and those who hold the views so eloquently put forward in this

Endler himself is sanguine that "as our knowledge...increases, perhaps natural selection will become easily detectable at the biochemical and even the molecular level". Although ecological genetics has a

long way to go before this hope will be fulfilled, it is nevertheless true that a hypothesis that selection acts on a particular system is, like the search for the North West Passage, intrinsically productive even if it is wrong. All too often great pyramids of theory have been balanced on a mere assumption that selection is unimportant: the neutral theory has been much more of a stimulus to theoretical than to experimental studies of evolution. Theory frequently asks us to measure the unmeasurable, and experiments on the genetics of populations in nature are often designed in such a way as to produce results which cannot be interpreted. What is needed is a joint approach to the problem of the importance of selection in evolution: to use one of the quotations from Dr Johnson which preface each chapter, \ there is nothing

more pleasant, or more instructive, than to compare experience with expectation, or to register from time to time the difference between idea and reality. It is by this kind of observation that we grow daily less liable to be disappointed.

Natural Selection in the Wild is a unique blend of ideas about evolution set against the reality of studying it in nature. All evolutionists should read the book: it will disappoint none of them, whatever their preconceptions about the importance of natural selection.

THE INVAGINATE GASTRULA AND THE PLANULA

A giddy little Gastrula, gyrating round and round, Was thought to show the way we got our enteron profound: A little whirlpool in its wake maintained a tasty store, A pocket sank to lodge it all, and left a blastopore.

As a larval epigram this description earns a prize, But as sketching adult ancestry can only win surprise, And when you note all early orders fixed upon the rocks, You feel a slight embarrassment, the first of many shocks.

The foremost inconsistency is the simple, solid fact That the Hydrozoan larva, the mouthless *Planula*, is packed With a jumbled mass of gastric cells that drop in, slow or fast, And show no slightest cavity till the larval stage has passed.

The larva then becomes attached, and shortly stands erect, Nourished by the yolky stores the inner cells eject: Their shrinkage leaves a growing space, the early enteron, Round which a layer of cells remains, and lines the outer one.

Some tentacles are sprouted then, say 2, then 4 and 8, And not till all is ready does the mouth break through quite late. If mouth and gut arose at first from one invagination, What roundabout procedure's here! What needless complication!

Invagination surely is a thing of later date—Procedure speeded up to suit the embryonic state:
The cells as loose irregulars build up the lower grades,
And yield but slowly, step by step, to organised brigades.

Reason in rhyme — this poem is an attack by Walter Garstang on Haeckel and his followers, who, in support of their "biogenetic law", invented an ancestor for all metazoans (the Gastrea theory) and claimed to be able to trace the evolution of the gut from a dimple in the surface of the primordial metazoan. It is reproduced from a new paperback reprint of Garstang's Larval Forms and Other Zoological Verses, published by University of Chicago Press. Price is \$5.95, £4.95.

The mystery of declining tooth decay

from Mark Diesendorf

Large temporal reductions in tooth decay, which cannot be attributed to fluoridation, have been observed in both unfluoridated and fluoridated areas of at least eight developed countries over the past thirty years. It is now time for a scientific re-examination of the alleged enormous benefits of fluoridation.

FLUORIDATION consists of raising the concentration of the fluoride ion F⁻ in water supplies to about 1 part per million (p.p.m.) with the aim of reducing dental caries (tooth decay) in children. In fluoridated areas, there are now many longitudinal (temporal) studies which record large reductions in the incidence of caries¹. The results of these and of fixed time surveys have led to the 'fluoridation hypothesis', namely that the principal cause of these reductions is fluoridation.

Until the early 1980s, there had been comparatively few longitudinal studies of caries in unfluoridated communities. Only a small minority of the studies in fluoridated areas had regularly examined control populations, and there seemed to be little motivation to study other unfluoridated communities. But during the period 1979-81, especially in western Europe where there is little fluoridation, a number of dental examinations were made and compared with surveys carried out a decade or so before. It soon became clear that large reductions in caries had been

occurring in unfluoridated areas (see below). The magnitudes of these reductions are generally comparable with those observed in fluoridated areas over similar periods of time.

In this article, these reductions are reviewed and attention is also drawn to a second category of caries reduction which cannot be explained by fluoridation. This category is observed in children described by proponents of fluoridation as having been 'optimally exposed', that is, children who have received water fluoridated at about 1 p.p.m. from birth. The observation is that caries is declining with time in 'optimally exposed' children of a given age. In some cases, the magnitudes of these reductions are much greater in percentage terms than the earlier reductions in the same area which had been attributed to fluoridation.

The problem of explaining the two categories of reduction goes well beyond the field of dentistry: contributions from nutritionists, immunologists, bacteriologists, epidemiologists and mathematical

statisticians, amongst others, may be required.

Caries in unfluoridated areas

Table 1 lists over 20 studies which report substantial temporal reductions in caries in children's permanent teeth in unfluoridated areas of the developed world. In many of these cases, the magnitudes of these reductions are comparable with those observed in fluoridated areas and attributed to fluoridation.

Several of these studies give clues as to factors which are unlikely to be the main causes of the reductions. A comparison of the 1954 and 1977 dental health surveys in Brisbane^{2,3} indicates to a reduction of about 50% in caries, as measured by the number of decayed, missing and filled permanent teeth (DMFT) per child and averaged over the age groups, in the 23year period. The 1977 survey distinguished between children who took fluoride tablets regularly, irregularly or not at all. Although there were differences in caries incidences between the three categories (which could reflect factors unrelated to fluoride levels), even the "no tablet" group had on average 40% less caries experience than that recorded in 1954. So fluoride tablets were not the principal cause of the reductions observed in Brisbane.

The first Sydney study⁴ showed that children with "naturally sound" teeth increased from 3.8% in 1961 to 20.2% in 1967 and 28% in 1972. The paper, which was titled enthusiastically "The Dental Health Revolution", was originally used widely to promote fluoridation in Australia. The authors stated that: "Almost certainly, the availability of fluoride both in tablet form and delivered through town water supplies has been the predominant factor.... These very large reductions represent a modern triumph of preventive health care"4. Yet the major proportion of the reported improvement had already occurred before Sydney was fluoridated in 1968. Moreover, no evidence was presented that fluoride tablets were widely used in the 1960s. Fluoride toothpaste was only introduced into Australia in 1967³. Although the index "naturally sound" teeth is unsuitable for more detailed

^{*} Unpublished communication from J. Tee (1980), Area Dental Officer, Gloucestershire, to R. J. Anderson et al.³⁷

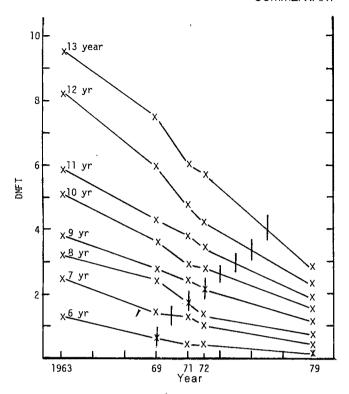

Fig. 1 Decline in caries, as measured by DMFT, in Tamworth, Australia, for children in age groups 6 years to 13 years. Data compiled from refs 14, 15. The vertical line cutting graph for each age group denotes year at which maximum possible benefit from fluoridation was reached.

Tamworth was fluoridated in 1963.

studies which distinguish decayed, missing and filled teeth, the populations examined were very large (over 9,000 children at each examination) and the results clear-cut.

A second Sydney study⁵ used the DMFT index, but was irrelevant for establishing any link with fluoridation, since it reported only on examinations in 1963 and 1982, but not around 1968 when Sydney was fluoridated. As in several other fluoridation studies, the key data were either not collected or not reported⁶. Although the two Sydney papers have an author in common (James S. Lawson, a senior officer of the New South Wales Health Commission), the second paper does not even cite the first. This suggests that, once it became clear that the first Sydney study contained evidence unfavourable to fluoridation, it was a source of embarrassment to some fluoridation proponents who are apparently trying to denigrate it.

However, independent confirmation of the large reductions in caries before fluoridation reported in the first Sydney study⁴ is readily obtained by comparing the results of two surveys^{7,8} separated by 20 years by Barnard. These surveys showed that the mean DIMF index ('1' denotes a permanent tooth which cannot be restored) for school children aged 13 and 14 declined from 11.0 in 1954-55 to 6.0 in 1972. The four years from 1968, when fluoridation commenced in Sydney, to

1972, would not have contributed significantly to the decline in caries prevalence in this age group⁹.

The authors of one of the British studies cited in Table 1 point out that sales of fluoride toothpaste in the United Kingdom were less than 5% of total sales in 1970, but rose to more than 95% of sales in 1977. They quote unpublished annual data from unfluoridated parts of Gloucestershire, collected from 1964 onwards, which show substantial improvements in children's teeth before the use of fluoride toothpaste became significant.

Many of the studies in the Netherlands, reviewed by Kalsbeek¹¹, were carried out to evaluate the effectiveness of the school

dental health programme. Temporal reductions in DMFT of about 50% occurred between 1970 and 1980, whether or not the children had taken part in the dental health education program. Kalsbeek also reviewed the use of fluoride tablets and toothpaste and concluded from the data that "factors other than the effects of different fluoride programmes must play a role."

The study in the partly fluoridated city of Auckland, New Zealand¹², examined the influence of social class (which reflects environmental and lifestyle factors, such as diet) as well as fluoridation on dental health as measured by the levels of dental treatment received by children. The paper showed that treatment levels have continued to decline in both fluoridated and unfluoridated parts of the city and that these reductions are related strongly to social class, there being less caries in the "above average social rank" group than in other children. Thus the main ethical argument for fluoridation, that it should assist the disadvantaged, is not borne out by this study.

Fluoridation's benefits

On 15 December 1980, the Dental Health Education and Research Foundation, one of the main fluoridation promoting bodies in New South Wales (NSW), issued a press release entitled, "Fluoridation dramatically cuts tooth decay in Tamworth" 13. This document, which highlighted results of a study conducted by the Department of Preventive Dentistry, Sydney University, and the Health Commission of NSW, stated in part:

Tamworth's water supply was fluoridated in 1963, and the last survey in the area was conducted in August 1979. It shows decay reductions ranging from 71% in 15-year-olds to 95% in 6-year-olds... All those surveyed were continuous residents using town water.

The "95%" reduction actually corresponded to a reduction in DMFT from 1.3 in 1963 to 0.1 in 1979¹⁴, which is 92%. The press release implied incorrectly that all this reduction was due to fluoridation. However, it has been claimed ever since

Table 2 Extent of fluoridation in Australia, 1977 and 1983

State or territory	. Capital city	Year city fluoridated*	% Of state fluoridated†	% Of state fluoridated† in 1983
ACT	Canberra	1964	100	100
Tasmania	Hobart	1964	74	77
NSW .	Sydney	1968	81	81
WA	Perth	1968	83	83
SA	Adelaide	1971	71	70
Victoria	Melbourne	1977	0.7 then 73	71
Queensland	Brisbane	Not fluoridated	10	5

^{*} Each capital city has the majority of the population of its state or territory.

[†] That is, the percentage of population of state/territory which drinks fluoridated water. Data from Annual Reports of Director-General of Health, for example ref. 17.

the commencement of fluoridation that the maximum possible benefits from fluoridation are obtained in children who have drunk fluoridated water from birth. Sixyear-olds would have done this by 1969, when, according to the published data15, they had a DMFT index of 0.6. The further reduction in caries in optimally exposed 6-year-olds, observed in years following 1969, cannot be due to fluoridation.

Thus, one can say that at best fluoridation could have approximately halved the DMFT rate in 6-year-olds between 1963 and 1969. (Since there was no control population, one could also say that at worst fluoridation might have had no effect in that period.) But from 1969 to 1979, caries in 6-year-olds was reduced a further 83%, by some other factor(s) than fluoridation.

Figure 1 shows that the unknown factors caused in children of each age from 6 years to 9 years similar large reductions in caries. Unfortunately, there are no published data for Tamworth beyond 1979 or in the years between 1972 and 1979, and so it cannot be confirmed whether the large reductions observed^{14,15} from 1972 to 1979 in children aged 10 to 15 were also due to these unknown factors.

A similar reduction beyond the maximum possible for fluoridation is observed for children of each age from 6 to 9 in the published data from Canberra¹⁶. which cover the period from 1964, the stated year of fluoridation, to 1974. In particular, DMFT rates declined by 50% in 6-year-olds from 1970 to 1974 and by 54% in 7-year-olds from 1971 to 1974. These reductions in optimally exposed children cannot be due to fluoridation. Published post-1974 data are needed to check on further reductions in optimally exposed children aged over 9 years.

From 1977 onwards, data have been systematically collected from the school dental services in each Australian state and territory^{9,17}. Table 2 shows the degree of fluoridation in each of these states/territories in 1977 and 1983 and also the dates of fluoridation of the capital cities of these regions. Each of these cities dominates the population of the state or territory in which it lies. The evidence presented in Fig. 2 and Table 2 suggests that states and territories which had been extensively fluoridated for at least 9 years before 1977 (Tasmania, Western Australia and New South Wales) had qualitatively similar large reductions in caries from 1977 to 1983 as a state which was only extensively fluoridated in 1977 (Victoria) and a state which had a small and declining fraction of fluoridation (Queensland). Although the results of the school dental health survey are recorded by age and state, the data have only been published^{9,17,18} so far for ages 6-13 averaged in each state, or for each age for the whole of Australia. There is evidence that the use of fluoride tooth-

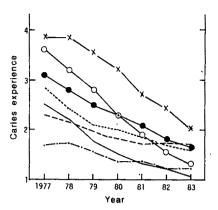

Fig. 2 Decline in the average number of (permanent) teeth per child with caries experience in each Australian state and the Australian Capital Territory as observed in school dental services17. 'Caries experience' can be one or more decayed, missing or filled teeth, and consists of an average for children aged 6-13 years. See Table 2 for information on the extent of fluoridation in each state/territory in 1977 and 1983 and the year when the main population centre of each state/territory was fluoridated. ×, Victoria; ○, Tasmania; ●, Queensland; - - ---, SA; ---, NSW; ---, WA; ·-·-·, ACT.

paste in Australia reached a high plateau around 1978, so these observed reductions in caries can be due neither to fluoride toothpaste9 nor to fluoridated water.

It is to be hoped that similar data on caries reductions in "optimally exposed" children will be sought in other fluoridated countries. In a region of Gloucestershire, United Kingdom where the main water supply was naturally fluoridated with 0.9 p.p.m. fluoride until 1972, reductions in caries of 51% were observed in 12-yearold children between 1964 and 197919. Factors other than fluoridated water must have caused these reductions. After 1972, the main water supply was drawn from a bore with less than 0.2 p.p.m. fluoride, so a recent survey of caries there would be of great interest.

Benefits overestimated?

In some fluoridated areas (for example Tamworth, Australia), temporal reductions in caries have been wrongly credited to fluoridation. The magnitude of these reductions is similar in both fluoridated and unfluoridated areas, and is also generally comparable with that traditionally attributed to fluoridation. Can it be concluded that communities which prefer not to fluoridate, either because of concern about potential health hazards²⁰⁻²⁵ or for ethical reasons (for example compulsory medication; medication with an uncontrolled dose), do not necessarily face higher levels of tooth decay than fluoridated communities? In other words, is it reasonable to ask whether it could be generally true that a major part of the benefits currently attributed to fluoridation is really due to other causes?

Such a hypothesis would seem to be possible in principle because it is well known that fluoridation is neither 'necessary' nor 'sufficient' (the words between inverted commas being used in the formal logic sense) for sound teeth; that is, some children can have sound teeth without fluoridation, and some children can have very decayed teeth even though they consume fluoridated water25.

To confirm or refute the hypothesis, it is necessary (but not 'sufficient') to examine the absolute values of caries prevalence in fluoridated and unfluoridated areas. If it is true that the absolute values of caries prevalence in some unfluoridated areas are comparable with those in some unfluoridated areas of the same country, then the hypothesis is supported (but not proven), and there would be a strong case for the scientific reexamination of the epidemiological studies which appear to demonstrate large benefits from fluoridation.

The earliest set of studies comparing caries in fluoridated and unfluoridated areas were time-independent surveys of caries prevalence in areas with 'high' natural levels of fluoride in water supplies, conducted by H. T. Dean and others in the United States²⁶. The surveys purported to show that there is an "inverse relationship" between caries and fluoride concentration. From the viewpoint of modern epidemiology, these early studies were rather primitive. They could be criticized for the virtual absence of quantitative, statistical methods, their nonrandom method of selecting data and the high sensitivity of the results to the way in which the study populations were grouped²⁵.

Results running counter to the alleged inverse relationship have been reported time-independent surveys naturally fluoridated locations in India², Sweden²⁸, Japan²⁹, the United States³⁰ and New Zealand^{31,63}. The Japanese survey²⁹ found a minimum in caries prevalence in communities with water F-concentrations in the range 0.3-0.4 p.p.m.; above and below this range, caries prevalence

increased rapidly.

These surveys²⁷⁻³¹ also selected their study regions nonrandomly. But recently Ziegelbecker32 attempted to make a selection close to a random sample by considering 'all' available published data on caries prevalence in naturally fluoridated areas. His large data set, which includes Dean's as a sub-set, comprises 48,000 children aged 12-14 years drawn from 136 community water supplies in seven countries. He found essentially no correlation between caries and log of fluoride concentration. The surveys²⁷⁻³² are generally omitted from lists1 of studies on the role of fluoridation in caries prevention.

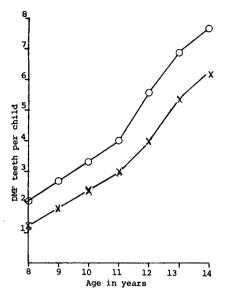

Fig. 3 The variation with age of decayed, missing and filled permanent teeth (DMFT) in fluoridated test towns (×) and unfluoridated control towns (O) in Britain, graphed from data published by the UK Department of Health³³. Note that the rate of increase of DMFT is essentially the same in both groups. Children in the fluoridated areas have an average only one less cavity than children of the same age in the unfluoridated areas.

Further evidence can be drawn from Fig. 2. In 1983, the absolute value of caries prevalence in the Australian state of Queensland (which is only 5% fluoridated) was approximately equal to that in the states of Western Australia (83% fluoridated) and South Australia (70% fluoridated).

The classical British fluoridation trials at Watford and Gwalchmai were longitudinal controlled studies. In this regard they were better designed than the majority of other studies which have been conducted around the world. However, as in the case of almost all other surveys, the examinations were not 'blind'. The review of the British trials by the UK Department. of Health after 11 years of fluoridation showed that children in fluoridated towns had approximately one less DMFT (that is, essentially one less cavity) than children of the same age in unfluoridated towns (see Fig. 3). The rate of increase in caries with age was the same in both populations³³

Thus there are a number of counter-examples to the widely-held belief that "All studies show that communities where water contains about 1 p.p.m. fluoride have about 50% lower caries prevalence than communities where water has much less than 1 p.p.m. fluoride".

At this point the empirical data presented here may be summarized as follows. In the developed world:

- (1) there have been large temporal reductions in caries in unfluoridated areas of at least eight countries;
- (2) there have been large temporal reductions in several fluoridated areas which cannot be attributed to fluoridation;
- (3) the absolute values of caries prevalence in several fluoridated areas are comparable with those in several unfluoridated regions of the same country.

Hence there is a case for scientific reexamination of the experimental design and statistical analysis of those studies which appear to prove or "demonstrate" that fluoridation causes large reductions in caries. Indeed the few re-examinations which have already been done confirm that there are grounds for concern.

The original justification for fluoridation in the United States, Britain, Canada, Australia, New Zealand and several other English-speaking countries was based almost entirely on the North American studies, which were of two kinds. The limitations of the first set, the time-independent surveys conducted in naturally fluoridated areas of the United States²⁶, have been referred to above.

The second set of North American studies consists of five longitudinal studies-carried out at Newburgh, Grand Rapids, Evanston and Brantford (two studies)-which commenced in the mid-1940s. Only three of them had controls for the full period of the study. These studies were criticized rigorously in a detailed monograph by Sutton³⁴, on the grounds of inadequate experimental design (for example, no 'blind' examinations and inadequate baseline measurement), poor or negligible statistical analysis and, in particular, failure to take account of large variations in caries prevalence observed in the control towns. The second edition of Sutton's monograph contains reprints of replies by authors of three of the North American studies and another author, together with Sutton's comments on these replies. It is difficult to avoid the conclusion that Sutton's critique still stands. Indeed, this was even the view of the profluoridation Tasmanian Royal Commission³⁵. Yet, in major, recent reviews of fluoridation, such as that by the British Royal College of Physicians³⁶ these North American studies are still referred to as providing the foundations for fluoridation, and Sutton's work³⁴ is not cited.

An examination has just been completed of the experimental design of all of the eight published fluoridation studies conducted in Australia. One (Tasmania) is a time-independent survey. Four (Townsville, Perth, Kalgoorlie and the second Sydney study) are longitudinal studies with only two examinations of the test group and either no control or only a single examination of a comparison group. The remaining three studies (Tamworth, Canberra and the first Sydney study) have several examinations of the test group, but no comparison group at all. Thus there has not been a single controlled longitudinal study in Australia. (M.D., to be published). Moreover, it has been shown above that three of the Australian studies (the first Sydney⁴, Tamworth^{14,15} and Canberra16) inadvertently provide evidence V that some other factor(s) than fluoridation is/are playing an important role in the decline of caries prevalence.

Hence the hypothesis that fluoridation has very large benefits requires reexamination by epidemiologists, mathematical statisticians and others outside of the dental profession. The danger of failing to perform scientific research on the mechanisms underlying the large reductions in caries discussed in this paper is that the strong emphasis on fluoridation and fluorides may be distracting attention away from the real major factors. These factors could actually be driving a cyclical variation of caries with time³⁷. It is possible that the condition of children's teeth could return to the poor state observed in the 1950s, even in the presence of a wide battery of F-treatments.

Causes of caries reductions

Many of the authors who reported the reductions in unfluoridated areas acknowledged that the explanation has not yet been determined scientifically^{11,37-41}. It is after all much easier to perform a study which measures temporal changes in the prevalence of a multifactorial disease than to identify the causes of such changes.

Nevertheless, the authors of some of these studies have speculated that important causes of the reductions which they observe might be topical fluorides^{38,53} (such as in toothpastes, rinses and gels), fluoride tablets^{4,38}, school dental health programmes⁹, a lower *frequency* of sugar intake³⁹, the widespread use of antibiotics which may be suppressing *Streptococcus mutans* bacteria in the mouth⁴¹, the increase in total fluoride intake from the environment^{9,42}, or a cyclical variation in time resulting from as yet unknown causes³⁷.

The present overview has revealed that several of the studies contain evidence against some of these proposed factors. We have seen that the Brisbane study³ and

the Dutch review¹¹ suggest that fluoride tablets may not be important; the Sydney study⁴, one of the British studies¹⁰ and the Dutch review¹¹ each provides evidence against fluoride toothpaste; and the Dutch review11 found no benefit in their school dental health education programmes.

Although there is evidence that fluoride toothpaste cannot be an important mechanism of caries reduction in some of the studies reported here, it must be stated that, unlike the case of fluoridation, there are also a few well-designed randomised controlled trials which demonstrate substantial reductions in caries from fluoride toothpaste⁴³. Hence, the hypothesis can be made that topical fluorides sometimes improve children's teeth, although they are not necessary. So topical fluorides may comprise one of several factors contributing to the solution of the scientific problem of explaining the reduction in tooth decay.

Leverett⁴² has speculated that the caries reductions in his smaller set of unfluoridated locations may be due to "an increase in fluoride in the food chain, especially from the use of fluoridated water in food processing, increased use of infant formulas with measurable fluoride content, and even unintentional ingestion of fluoride dentifrices." This hypothesis cannot explain the reductions in prefluoridation Sydney⁴, or those in unfluoridated parts of Gloucestershire which started in the late 1960s¹⁰. The ingestion of fluoride toothpastes (and gels) by young children is well documented and could account for an intake of about 0.5 mg F per day in the very young⁴⁴. But the food processing pathway is unlikely to be significant in western Europe where there is hardly any fluoridation, and infant formulas which are made up with unfloridated water will give only small contributions. Thus it appears that Leverett's hypothesis may at best be relevant to a minority of the studies listed in Table 1.

Here, the working hypothesis is presented that fluoridation and other systemic uses of fluoride, such as fluoride tablets, have at best a minor effect in reducing caries: that the main causes of the observed reductions in caries are changes in dietary patterns, possible changes in the immune status of populations and, under some circumstances, the use of topical fluorides. Indeed, a promising explanation is that the apparent benefit from fluorides is derived from their topical action. Then, since fluoridated water has a fluoride ion concentration 10⁻³ times that of fluoride toothpaste, its action in reducing caries is likely to be much weaker.

It is known that immunity plays a role in the development of caries, as it does with other diseases. Research is currently in progress to try to develop a vaccine against caries⁴⁵⁻⁴⁷. None of the data presented in the present paper provides evidence against immunity as a factor.

Dentists often argue against changes in dietary patterns as a major factor, on the grounds that sugar consumption has remained approximately constant in most developed countries over the past few decades. However, this is a simplistic argument. First, crude industry figures on total sales of sugar in developed countries contain no information on the distribution of sugar consumption with age and time of day. The form of sugar ingested-for example in canned food, soft drinks or processed cereals-may also be important. Second, tooth decay is increasing together with increases in sugar and other fermentable carbohydrates in the diet in several developing countries^{48,49}. This was also the case with Australian aborigines, even when their water supplies consisted of bores containing fluoride at close to the "optimal" concentration for the local climate^{50,51} Third, there is more to diet than sugar. For instance, there is some evidence, even conceded occasionally by pro-fluoride bodies⁵², that certain foods which do not contain fluorides (for example wholegrain cereals, nuts and dairy products) may protect against tooth decay. So the whole question of the relationship between total diet and tooth decay needs much greater input from nutritionists and dietitians.

Perhaps the real mystery of declining tooth decay is why so much effort has gone into poor quality research on fluoridation, instead of on the more fundamental questions of diet and immunity.

The main body of this research was performed while the author was a principal research scientist in the CSIRO Division of Mathematics and Statistics, Canberra.

Pathogenesis of lentivirus infections

Ashley T. Haase

Department of Microbiology, University of Minnesota, 420 Delaware St, SE, Minneapolis, Minnesota 55455, USA

Following infection of animals or humans, lentiviruses play a prolonged game of hide and seek with the host's immune system which results in a slowly developing multi-system disease. Emerging knowledge of the disease processes is of some relevance to acquired immune deficiency syndrome (AIDS), which is caused by a virus possessing many of the characteristics of a lentivirus.

LENTIVIRUSES, a subfamily of retroviruses (Table 1), derive their name from the slow time course of the infections they cause in humans and animals¹⁻¹⁰. The persistence and spread of these viruses, despite host defences, and the origins and slow evolution of the diseases they cause, pose fascinating problems in pathogenesis which have assumed a new significance with the addition of the agent of acquired immune deficiency syndrome (AIDS) to the subfamily. This review summarizes the increasingly coherent picture of the pathogenesis of lentivirus infections, and discusses the relevance of these concepts to the behaviour and control of the AIDS virus.

Visna-maedi and central issues

Lentiviruses cause chronic diseases affecting the lungs, joints, nervous, haematopoietic and immune systems of humans and animals (Table 1). The prototypic lentiviruses, visna and maedi, derived their Icelandic names from the prominent symptoms (wasting and shortness of breath) of the neurological and pulmonary diseases they cause in sheep. In fact, it is the same virus² that is responsible for both maedi, the more prevalent pulmonary disease, and visna, a paralytic condition showing some resemblance to multiple sclerosis 11-15. These two diseases reached epidemic proportions in Iceland in the 1940s about a decade after the virus was inadvertently introduced into Iceland by sheep imported from Germany. An Icelandic physician, Bjorn Sigurdsson, investigated the outbreaks of visna and maedi, showed that a filterable agent caused them12, and discovered the long incubation period and protracted course of disease that distinguish slow infections¹⁶. Sigurdsson introduced the term slow infection¹⁷ to capture the novel timescale of disease and the experimental design needed to demonstrate transmissibility, thus setting the stage for the discovery of slow diseases in man¹⁸.

In natural and experimental infections of sheep (Fig. 1a), the aetiological agent of visna-maedi replicates at the site of entry (the lung in natural infections) and subsequently spreads via the bloodstream or by other routes, such as the cerebrospinal fluid (CSF). The infected animal mounts a defensive response which has both nonspecific components, such as phagocytic cells, and specific humoral and cellular-immune elements 19,20. These defence mechanisms are effective against extracellular virus but are generally unable to eradicate the infectious agent altogether. Virus persists in many organ systems and continues to circulate in blood and tissue fluids. In the lungs and central nervous system (CNS), tissue is destroyed in areas where inflammatory cells have collected, and eventually this burden of pathological change becomes apparent as shortness of breath or partial paralysis and weight loss. In natural infections, animals generally become symptomatic in the second year of infection and die after a protracted and progressive illness.

This brief description of the major events of infection in visna-maedi is intended to bring out three salient problems in understanding the pathogenesis of slow infections: (1) How does

virus persist and spread in the face of a vigorous and sustained immune response by the host? (2) What causes destruction of tissue? (3) Why do these pathological events evolve so slowly?

Virus gene expression and persistence

The best current explanation for the persistence of lentiviruses is the immunologically silent nature of the infection. Most infected cells harbour the virus in a latent state in which viral antigens are not produced in sufficient quantities for detection and destruction of the infected cell by immune-surveillance mechanisms²¹. To show the magnitude of these damping effects, evidence for and molecular measures of the restricted virus gene expression in vivo have been set against a background of the growth of virus under permissive conditions in tissue culture in Figs 1 and 2 and Table 2. In tissue culture, visna virus reproduces rapidly to high titre and destroys the host cell^{22,23}. In this lytic and productive cycle, genetic information is transferred from the RNA genome of the infecting virus to a DNA intermediate

Table 1 Retrovirus subfamilies					
Subfamily	Disease	Natural hosts			
Oncoviruses	Cancer	Man, animals, birds and reptiles			
Spuma viruses	Inapparent infections	Man, animals			
Lentiviruses	Slow infections	Man, animals			
Visna-maedi virus	Pneumonia, meningoencephalitis	Sheep, goats			
Progressive pneu- monia virus (PPV)	Pneumonia	Sheep, goats			
Caprine arthritis encephalitis virus (CAEV)	Arthritis, pneumonia, meningoencephalitis	Goats, sheep			
Zwoegerziekte	Pneumonia, meningoencephalitis	Sheep			
Equine infectious anaemia virus (EIAV)	Fever, anaemia	Horses			
AIDS virus (HIV)	Immune deficiency, encephalopathy, myelopathy	Man			

The retrovirus subfamilies shown are currently accepted taxonomic divisions¹²¹. The EIAV and AIDS virus are provisionally included in the lentivirus subfamily because they, too, cause slow infections and have other properties in common with visna-maedi¹²²⁻¹³¹: cell fusion and other cytopathic effects in tissue culture; virion morphology; polypeptide composition; large envelope glycoproteins; shared antigenic determinants in the major structural protein (gag); similar size and structure of their genomes; nucleotide and amino-acid sequence homologies largely confined to conserved regions of gag-pol.

in the cell^{24,25} which serves as a template for the synthesis of thousands of copies of genomic and messenger RNAs (Table 2a). The latter are translated into millions of copies of structural virion proteins²⁶ and infectious progeny (50–100 per cell) subsequently assemble at the cell surface. The infected cells degenerate, either individually or after fusion²⁷, within 3 days.

By contrast, replication of virus in animals is highly focal and unproductive, even in relatively homogeneous populations of cells which serve as substrates for permissive growth in tissue culture: the number of copies of viral RNA in choroid plexus of infected animals is about two orders of magnitude less than in infected choroid plexus cells in culture (Table 2). Synthesis of viral RNA, antigens and virus is confined to one in a hundred to thousands of cells (Table 2b)²⁸. This focal and restricted growth cycle has been revealed by methods for quantitative analysis of virus replication at the single-cell level (in situ hybridization)²⁹ and, more recently, by methods that combine macroscopic screening of tissue with single-cell resolution (Fig. 2)30. The fundamental question of why virus growth should be so different in cells in culture from that in tissues is unanswered, but viral RNA synthesis has been defined as the major point in the virus growth cycle at which virus gene expression is blocked28.

Visna thus has two kinds of life cycle, somewhat analogous to bacteriophage λ in *Escherichia coli*: a productive and lytic life cycle in vitro and a latent life cycle in sheep, figuratively referred to as lysogeny on a grand scale³. This is probably overstated, as visna virus is not integrated into the host cell genome, àt least in tissue culture³¹, but it does epitomize the notion of the clandestine state of the virus as the mechanism by which it eludes the host's defences.

Trojan horse mechanism

A similar mechanism can be invoked to explain the continued spread of virus in the bloodstream, cerebrospinal fluid and other fluids that contain immune cells and neutralizing antibody. In this mechanism, a mobile cell, predominantly if not exclusively a monocyte^{32,33} in the case of visna virus, conceals the virus genome and conveys it without detection to other sites. Evidence for this Trojan horse mechanism again comes from in situ hybridization analyses of CSF, where infected cells are concentrated³². (The frequency of leukocytes carrying visna virus in the bloodsteam—about 1 in 10⁶ cells—is too low to be detected directly.) The CSF data³² provide evidence of (1) restricted levels of viral RNA accumulation in monocytes; (2) circulation of the latently infected monocytes in tissue fluids containing neutralizing antibody; and (3) transfer of infectious virus between monocytes and choroid plexus cells under conditions of close contact between the cells. These data satisfy the major predictions of the Trojan horse hypothesis.

Inapparent infections and latency

The theme of restricted virus gene expression is the dominant motif of lentivirus infections. In animals, infections are frequently not apparent, with no obvious pathological sequelae for periods that approximate the normal lifespan of the host. In the United States, for example, lentivirus infection of sheep is widespread and probably largely asymptomatic³⁴. There are flocks of sheep in Germany in which antibodies to virus are present in 50 per cent of the serum samples³⁵ and in which clinical symptoms of maedi have never been observed. Importation of silently infected sheep like these from Germany was presumably responsible for the outbreaks of maedi and visna in Iceland⁴.

The AIDS virus also establishes persistent and non-cytopathic infections in normal human lymphocytes³⁶. In the persistently infected cultures, virus production may be absent or limited (but can be induced), in keeping with the definition of latency³⁷. By extrapolation, similar virus-host cell interactions provide a mechanism for the AIDS virus to escape neutralization and

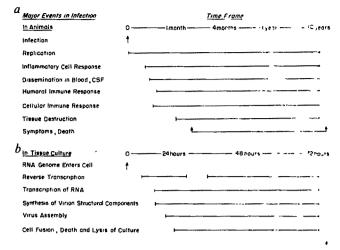

Fig. 1 Time course of animal lentivirus infection. The major events and strikingly different timescale of infection in animals (a) and tissue culture (b) can be seen.

other defences, but also a basis for the comforting observation that inapparent infection and a carrier state are common in infected patients³⁸.

Population spread

Animal lentivirus infections are transmitted between animals, probably by virus inside monocytes and macrophages in secretions (little if any cell-free virus is detectable). The aetiological agents of visna and maedi enter adult sheep by the respiratory route and lambs by a gastrointestinal route in colostrum^{2,4}. The appearance of disease in epidemical form requires special conditions such as those in Iceland, where sheep from many parts of the island are housed together for several days each year². This practice may have been as important in the rapid spread of the disease as the greater susceptibility of the Icelandic than German sheep to lentivirus infection.

AIDS is transmitted similarly. Virus is introduced into the bloodstream through sexual contact, intravenous drug administration with contaminated needles or administration of blood and blood products³⁶. It is not known whether the virus is transferred inside cells, but this is obviously of great importance in predicting the efficacy of conventional vaccine strategies to interdict further spread of AIDS. As in visna, perinatal transmission is also important, although it is not known whether this occurs in utero or postnatally.

There is no evidence of germline transmission of animal lentiviruses from mother to offspring, and endogenous lentiviruses are exceptional³⁹, in contrast to the situation with

Table 2 Comparison of the growth of visna virus in animals and in tissue culture

Type of infection	Cells positive for viral RNA (%)	Average no. of copies of viral RNA per infected cell	Cells with viral antigen (%)
a, Tissue culture (choroid plexus cells 3 days after infection)		5,000	90
b, Sheep (choroid plexus, alveolar macrophage monocytes, glial cells to 3 weeks after infec	; 3 days	50-150	0.001

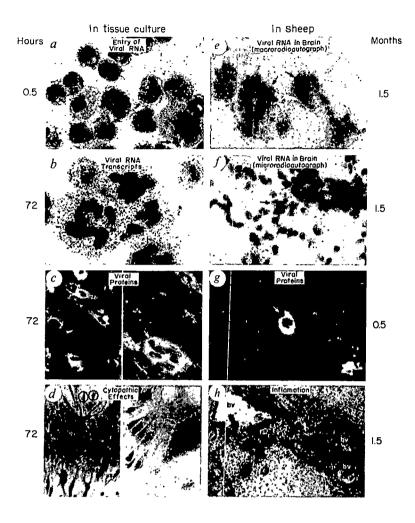

Fig. 2 Life cycles of an animal lentivirus in tissue culture and sheep. a, b, Autoradiographs of visna virus RNA detected by in situ hybridization. The number of copies of viral RNA in individual cells is proportional to the number of grains over the cell and the length of exposure2 At 0.5 h after infection (at a multiplicity of infection of 3 plaque-forming units per cell) about 30 copies of viral RNA enter the cell, often apparently inside a vacuole (arrows, a). By 72 h the cells contain about 5,000 copies of viral RNA²⁶, often in giant cells. Visna virus RNA can be localized anatomically in infected animals to regions surrounding the ventricles (arrows, e) using combined macroscopic-microscopic screening³⁰. In this method whole brain sections are hybridized to a virus-specific probe labelled with 125 I. The γ emission of 125 I produces a latent image of viral RNA on X-ray film placed against the tissue section after hybridization. The single-cell location of viral genes is determined from a microscopic autoradiograph produced by coating the section with nuclear track emulsion. The Auger electrons emitted by ¹²⁵I produce latent images with good resolution at the cellular level. The average copy number in the cells in the brain is about two orders of magnitude less than that in infected tissue culture (for example, number of grains over the cell in tissue culture 72 h after infection requires an exposure of a few hours; for a probe of the same specific activity, about 3 weeks would be needed to produce the number of grains in the cells in brain)30. In tissue culture there are ~106 copies of major viral protein (gag) easily detected in most cells by immunofluorescence with monospecific antibodies (c; the arrow indicates a giant cell with the visna gag polypeptide in the cytoplasm)4,127 Only rare cells with viral antigens can be detected in the infected animal (g). The infection in tissue culture leads directly to cell death with lysis of the culture in 72-96 h (d). Arrows indicate giant cells in various states of degeneration; individual dying cells are circled. In animals, tissue damage accumulates over months to years (h) and is indirectly caused by inflammatory cells (the dark-staining lymphocytes, plasma cells, monocytes, macrophages that surround the blood vessles (bv) and collect in foci in the tissue of this section of brain from a paralysed sheep¹⁻⁷.

oncogenic retroviruses. The exogenous nature of lentiviruses may reflect their infrequent opportunities to interact with the host genome. Only a few cells are infected in the animal, replication is restricted²⁸ and integration may be rare³¹. The failure of the viral genome to form covalent linkages with the host chromosome probably has a structural basis, as the topological precursor for retrovirus integration is likely to be circular DNA⁴⁰, and in cells infected with visna virus circular molecules are rare (the predominant structure is a nicked or gapped linear duplex)⁴¹. That is not to say that integration of lentivirus genomes cannot occur—integrated as well as unintegrated forms of AIDS virus⁴², equine infectious anaemia virus (EIAV)⁴³ and caprine arthritis and encephalitis virus (CAEV)⁴⁴ have been described.

Variant and common determinants

Antigenic variation is an additional or alternative mechanism for the persistence and spread of the lentiviruses. In this instance, the emergence of mutant viruses with an altered envelope glycoprotein, the antigen to which neutralizing antibody is directed⁴⁵, is the postulated mechanism by which virus temporarily escapes immunological inactivation. Gudnadottir's proposal that 'antigenic drift' might account for the survival of visna virus for such a long time in infected animals² was subsequently supported and fully developed by Narayan and his collaborators. They showed that antigenically distinct viruses could be isolated from sheep persistently infected with visna virus⁴⁶, and that these variants arise by point mutations in the *env* gene, which encodes the virion envelope glycoprotein^{45,47}. In visna,

however, variants do not replace the infecting serotype by antibody selection and, in most long-term infections, the inoculum virus strain persists and spreads without the emergence of antigenic variants^{48,49}. For these reasons it seems unlikely that antigenic variation is a necessary or important means of dissemination of visna virus.

For EIAV, the case for antigenic variation as an important mechanism of virus dissemination is more persuasive. There are cycles of virus replication in which cell-free virus is isolated from serum or plasma, and each new isolate from a cycle is refractory to neutralization by antibody that neutralized previous isolates^{50,51}. This immunologically dictated succession fulfils the expectations of the antigenic variation model for persistence and spread of viruses, and, as in visna virus infections, occurs primarily through point mutations in the env gene⁵². But this is not the sole basis for persistence and spread. By the end of the first year, cyclic replication of EIAV is superseded by an inapparent carrier state in which continued dissemination of virus within the host, or to new hosts, is again accomplished by latently infected macrophages⁹. Because this conversion to a Trojan horse mechanism of spread may be a consequence of production of antibody to all strains of EIAV, identification of these common antigenic determinants for neutralization would clearly be important in designing broadly effective vaccines.

It would be premature to predict the role of antigenic variation in AIDS infections, but isolates of the AIDS virus from different individuals differ genotypically⁵³, and this genomic diversity is greatest in the region of the *env* gene⁵⁴. If these genetic changes

are mirrored phenotypically, it will pose serious problems for vaccine development and provide an additional mechanism for the AIDS virus to persist and spread in individuals and populations.

Immunopathogenesis

Pathological changes in lentivirus infections are for the most part indirectly mediated by the immune and inflammatory response of the host. In visna, the coordinate reduction of inflammation and tissue lesions⁵⁵ with immunosuppression suggests that it is the inflammatory cell response (Fig. 2) that causes tissue damage. In the brain, this process is demyelinating¹¹⁻¹⁵ because at least one of the infected cell targets is the oligodendrocyte⁵⁶, the cell in the nervous system which provides the myelin sheath (identified unambiguously by a new method that combines immunocytochemistry, cell-specific antibodies and in situ hybridization⁵⁷; Fig. 3). The rare infected cell containing viral antigen probably provokes and sustains this inflammatory response⁵⁶, which then causes tissue damage by mechanisms that are not understood in any detail but could involve interleukin-mediated amplification of the response with indiscriminate damage to uninfected cells ('innocent bystanders') in the area. Lesions in the lungs and joints of infected animals in maedi virus and CAEV infections are also the result of the exuberant inflammatory response. In the lung, infiltration of lymphocytes and monocytes into the alveolar wall interferes with gas exchange; in the joints^{58,59}, the inflammatory cell infiltrate leads to the destruction of the cartilage perhaps by activating chondrocytes to elaborate matrix degrading factors⁶⁰, much as in rheumatoid arthritis.

Both lymphoproliferative changes (enlargement, necrosis) and immune complexes participate in the immunopathology of equine infectious anaemia^{9,61}. The characteristic anaemia is the result of phagocytosis and haemolysis of erythrocytes that first become coated with a viral haemagglutinin and then with antivirus antibody and complement. Circulating immune complexes of EIAV and antibody also elicit fever and cause glomerulone-phritis when they are deposited in the kidney. The, as yet unexplained, glomulerosclerosis and thrombocytopenic purpura of AIDS may similarly be immune complex diseases^{62,63}.

Immunopathology, however, cannot account for all the manifestations of lentivirus infections. There is an inflammatory component in the progressive encephalopathy that occurs frequently in children and adults with AIDS⁶⁴⁻⁶⁶, but in AIDS encephalopathy and myelopathy⁶⁷, inflammation is overshadowed by vacuolation and degenerative changes that are more like those in a paralytic disease of mice caused by some types of murine leukaemia viruses⁶⁸.

Immunodeficiency and cachexia

The agent of AIDS differs most profoundly from the lentiviruses of animals in its effects on the immune system. Immunodeficiency is the hallmark of AIDS^{10,69}, whereas in animal lentivirus infections the immune response is relatively normal or selectively impaired. (In natural US infections, particularly with CAEV, animals ordinarily produce little if any neutralizing antibody⁷⁰.) Until recently, the reasons for this distinction seemed relatively straightforward: the AIDS virus homes to a receptor on the surface of helper T cells^{71,72} and was thought to cause AIDS by destruction and depletion, or dysfunction, of this central element of the immune system. The animal lentiviruses infect monocytes in such small numbers that the impact on immune function is minor³².

It is becoming increasingly evident that this view is oversimplistic, inasmuch as infection of T4 lymphocytes (about 1 positive cell in 20,000-100,000 by in situ hybridization⁷³) is as infrequent in AIDS as it is in visna. To account for the large effects on the absolute number of T4 cells and immune function in AIDS, more complex mechanisms need to be invoked, including some that recall the theme of immunopathology in lentivirus

Immunocytochemistry with anti-oligodendrocyte antibody in situ hybridization Radioautography

Fig. 3 Determination of virus host cell tropism by the simultaneous detection assay⁵⁷. Brain sections from a paralysed sheep infected with visna virus were reacted with anti-oligodendrocyte antibody, and the reaction was visualized by immunocytochemical methods. After in situ hybridization with a visna virus-specific probe, the developed autoradiograph was examined to locate cells (oligodendrocytes) which stained with the antibody and also had an increased number of silver grains such as that shown in the figure. This method identifies the oligodendrocyte unambiguously as one of the types of cells infected by visna virus⁵⁶.

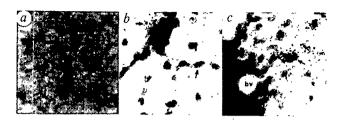

infections. For example, viral envelope glycoprotein shed from productive cells could make large numbers of uninfected cells targets for an autoimmune response directed to viral antigen bound to the T4 receptor. Alternatively, the network of interactions in the immune system should in time lead to an antiidiotypic response to antibody to the viral glycoprotein. This anti-idiotypic antibody might also be directed against the T4 antigen and viral receptor. This hypothetical reconstruction of the immune response provides a rationale for understanding the production of anti-lymphocyte antibodies in AIDS⁷⁴, and a basis for a paradoxical and potentially hazardous approach to treatment by immunosuppression⁷⁵. The latter could also theoretically relieve a block in the expansion, differentiation or function of T4 cells mediated by another subset of lymphocytes infected with the AIDS virus. Just as plausible, however, are direct mechanisms leading to immunodeficiency, for example, continued recruitment of uninfected T4 lymphocytes into the infectious process, destruction of precursors or the release of immunosuppressive virion components analogous to the p15E protein of feline sarcoma virus 76,77.

One of the unexplained symptoms of infection, the cachexia or wasting ('slim disease' is the name given to one form of AIDS in Uganda⁷⁸), might be partly attributable to interactions of lentiviruses with macrophages. In addition to inanition from concurrent enteropathic infections (possibly including AIDS virus) and diarrhoea which contribute to these manifestations of the infection, lentiviruses might, as the result of infection of monocytes, cause release of cachexin, a factor that inhibits adipocyte gene expression and the production of lipogenic enzymes⁷⁹.

Form and tempo of pathology

Visna virus gene expression is markedly curtailed in most infected cells in tissues²⁸, but there are a few cells in which levels of viral RNA approach those in productively infected tissue culture⁵⁶. These gradations in gene expression (Fig. 4) are tightly correlated with detection of viral antigens, the intensity of the inflammatory response, and tissue damage, as would be expected if gene expression determines the form and tempo of pathology. At one end of a spectrum of virus gene expression are a silent majority of infected cells with minimal levels of viral RNA and antigens, enabling the virus to persist and spread. Towards the other end of the spectrum is the occasional cell with higher levels of viral RNA and the antigens responsible for the continuing inflammatory cell response and inadvertent destruction of tissue at a rate commensurate with the scanty production of the inciting antigens. At the extreme end of the spectrum is the lytic

Fig. 4 Quantitative in situ hybridization used to demonstrate correspondence between virus gene expression and inflammatory response. Brain sections from a paralysed sheep infected with visna virus were hybridized with a virus-specific probe. In the developed and stained microautoradiographs there is a gradient in gene expression that correlates with the intensity of inflammation. a, A region with no inflammation and background levels of hybridization; b, as the number of copies of viral RNA increases, larger numbers of grains appear over cells (arrows) adjacent to small collections of dark-staining mononuclear cells; c, the largest numbers of inflammatory cells around blood vessels (bv) and tissue are adjacent to infected cells (arrow) with grain counts equivalent to hundreds to thousands of copies of viral RNA typical of productive infections in tissue culture. Viral antigens are occasionally demonstrable in cells with the highest concentrations of viral RNA56

infection in tissue culture, where destruction of cells is a rapid and direct result of virus growth under permissive conditions of replication. These cytopathic effects are more likely to be due to the abundance of virion components (probably the envelope glycoprotein) capable of fusing and killing the cell from within and outside²⁷ than to the high concentrations of extrachromosomal DNA which have been advanced as one explanation for these cytotoxic effects of retroviruses⁸⁰; experimental conditions can be contrived in visna-infected tissue culture (blocking superinfection with antibody)⁸¹ where fusion and cell death occur at DNA concentrations equivalent to those in tissues²⁸ at which cytopathic effects are never observed.

Regulatory mechanisms and control

The major thrust of this review on lentivirus pathogenesis is that the major issues of persistence, spread and the rate and mechanisms of cell death translate into more objective questions about the factors that control lentivirus replication. Indeed, the central fact and unresolved mystery in visna is why the replication of virus is restricted in the same relatively homogeneous and non-dividing population of cells that supports abundant replication after explantation²¹ or in non-dividing cells in cultures derived from the same tissues81. Many factors have been investigated that might potentially account for restriction; they fall into two general categories (extracellular and intracellular), and pertain to tissue culture systems or living hosts. The latter is an important distinction, because there are many examples of regulatory mechanisms that operate in tissue culture but bear little relationship to reality. For instance, one can establish persistent infections in tissue culture with visna virus in which the cells contain high concentrations of viral antigens, whereas the concentrations are low in infected sheep (A.T.H., unpublished). Moreover, antigenic variants of visna virus appear in a logical succession based on antibody selection in vitro⁸², but not in infected animals^{48,49}; and gene dosage effects in tissue culture⁸¹ apparently do not operate in vivo⁸³. The discussion below therefore concentrates on regulatory mechanisms which meet the test of relevance at the organismal level and which might be exploited in the control of lentivirus infections.

Sanctuaries and vaccines

In natural and experimental visna, dissemination of virus by extracellular routes largely ceases with the appearance of neutralizing antibody¹⁹, acting perhaps in concert with viral inhibitory factors in serum and CSF^{84,85}. Neither humoral nor cellular immunity, however, plays a significant part in maintaining latency, since immunosuppression does not relieve the restriction in virus gene expression^{55,86}.

The experience with animal lentivirus vaccines is unfortunately too limited to give much direction to vaccine development. Veterinary practices of identifying infected sheep by serological testing and removing them from flocks have been successful in controlling lentivirus infections of animals^{1,7,87}. No vaccine for

visna or maedi is available because of intractable difficulties in developing an inactivated virus or envelope component vaccine that will induce neutralizing antibody. Vaccinated sheep do produce complement-fixing antibody but are not protected. Moreover, natural infections are transmitted to lambs by cells in the colostrum of mothers carrying neutralizing antibody. This mechanism of transmission and the possibility of cell-cell spread⁸⁸ would circumvent conventional strategies for disease control. Lentiviruses also take refuge from immune defences in the central nervous system. Thus, vaccines alone cannot be expected to be wholly effective in preventing lentivirus infection, but may favourably alter the outcome by reducing at the outset of infection the number of cells with the potential to contribute to pathological changes.

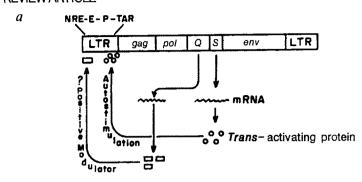

In AIDS, neutralizing antibody^{89,90} titres are low⁹⁰, virus in semen⁹¹ and saliva⁹² is partly cell-associated⁹³, and the brain is infected as a potential sanctuary for virus in a significant segment of the infected population^{64,94-96}. These considerations, and potential difficulties in vaccine development, underscore the importance of the practical measures and behavioural advice currently recommended to limit the spread of AIDS³⁶.

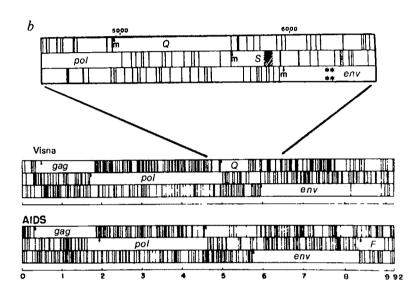

Intracellular mechanisms and antisense vaccine

Because viral gene expression directly or indirectly mediates cell damage, measures that limit gene expression should moderate or present the pathological consequences of infection. DNA synthesis is a logical point in the virus life cycle at which to intervene with drugs that inhibit reverse transcription or, like interferon, act intracellularly. The experience with the effects of inhibitors of viral DNA synthesis ^{97,98} and interferons ^{99,100} is limited to *in vitro* experiments which suggest that some benefit might be achieved ¹⁰⁰. In AIDS, inhibitors of reverse transcription have already undergone clinical trials, with demonstrable but temporary inhibition of virus replication and little alteration in clinical status ¹⁰¹. Sustained treatment with newer and less toxic drugs may induce long-term remissions ¹⁰².

Transcription and translation of the lentivirus genome are also potential targets for therapy. The major controlling elements for lentivirus gene expression are located at the 5' end (long terminal repeat, LTR) and centre of the genome (Fig. 5a, b). The lentiviral LTR, in common with other retroviruses, has promoter and enhancer domains and two additional domains, designated NRE and TAR in Fig. 5, which have negative or positive effects respectively on gene expression $^{103-105}$. The transactivating region (TAR) is responsive to a gene product encoded in a short open reading frame S (Fig. 5b) 103 . The transactivating gene product (TAT) of this open reading frame acts post-transcriptionally 106 to stimulate gene expression by 500-1,000-fold and is required for replication 107,108 . Modest stimulation by transactivation has also been described recently for visna virus 109 , which is comparable to that of the AIDS virus when the entire LTR of visna virus is used in the assay (K. Staskus, C. Rosen, W. Haseltine and A.T.H., unpublished). If transactivation has also been described as a sample of transactivation and A.T.H., unpublished).

Fig. 5 Speculations on control of lentivirus gene expression. a, Schematic illustration of a prototypic lentivirus genome and a speculative representation of control of gene expression. Transcription of the major genes of the virus is controlled by promoter (P) and enhancer (E) regions in the LTR. A trans-activating protein (O) encoded by the short open reading frame S binds to a region (TAR) to stimulate gene expression. The gene product of open reading frame Q also binds to the LTR to up-regulate transcription. The overall organization of the genomes of visna virus and the AIDS virus is shown in b with the controlling region in the centre of the genome with Q and S. (Modified from refs 103-110.) m, Initiator Met codon; F, an additional open reading frame in HIV (human immunodeficiency virus); asterisks in env indicate the hydrophobic signal sequence.

activation in visna is also effected post-transcriptionally, it could not account for the restricted gene expression in infected sheep which is primarily a result of diminished accumulation of viral RNA²⁸, but it could account for the discrepancy between the relatively high concentration of virus RNA in some cells and the lack of infectivity⁸³.

The reduction in transcription in infected animals was most recently speculated to be due to repressor activity of a putative DNA-binding protein, the basic and hydrophilic gene product of conserved open reading frames (Q) in visna¹¹⁰ and the AIDS virus¹¹¹⁻¹¹⁴. But there is now evidence that the Q gene product is a second positive regulatory factor, because deletion of Q slows the growth of the AIDS virus and delays the development of cytopathic effects¹¹⁵. Highly productive and rapidly progressive lytic infections may require co-expression of both factors, as might occur, for example, during activation of macrophages (CAEV) or lymphocytes^{116,117}.

One possible approach to the control of lentiviruses that anticipates the importance of the regulatory proteins encoded by the Q and S genes, and exploits antisense in mRNA¹¹⁸⁻¹²⁰, is the development of defective virus vectors which would stabilize the dormant state of infection. In one such project in progress in the visna model (K. Staskus, E. Retzel and A.T.H., unpublished), the trans-activating gene in infectious viral DNA is replaced by its antisense counterpart. Defective virus, produced by co-transfecting cells with the viral antisense DNA and with S gene DNA in an inducible expression vector, will have an identical host range to wild-type virus. It will therefore serve as a vector to introduce the antisense gene into cells already harbouring standard virus. In the co-infected cells, trans-activation should at first drive production of additional defective virus to

disseminate the antisense vector. Thereafter, the antisense vector should halt *trans*-activation and return the infected cells to a latent state. Of course, before there could be any assurance that the pathological consequences of infection may be prevented, this approach must overcome some theoretical and practical difficulties—particularly superinfection barriers in cells producing AIDS virus and the need to establish co-infection in a large pool of cells with a non-replicating virus.

Conclusions

The lentiviruses are responsible for slow infections of animals and man. Investigations of animal lentivirus infections have previously been directed to the inherently interesting issues of pathogenesis raised by this novel class of infections, parallels to such chronic diseases of man as multiple sclerosis and rheumatoid arthritis, and, to a much lesser extent, practical means of diagnosing, treating and preventing disease. With the knowledge that the causative agent of AIDS is a distant relative of the animal lentiviruses, these objectives have assumed a new and compelling urgency. Restricted gene expression is the general underlying mechanism in the persistence and spread of lentiviruses and the slow evolution of the diseases they produce. This restriction maintains the lentivirus genome in the cell in a covert state, and justifies the optimistic prediction that the commonest form of infection in AIDS, inapparent infection, will prevail for much, if not all, of the natural lifespan of the host. On a more pessimistic note, there is no guarantee that chronic infections will not ultimately progress to some form of illness; or that conventional approaches to prevention and treatment will be successful. These approaches may be frustrated by the ability of all lentiviruses to survive in intracellular and organ

(brain) sanctuaries or to elude host defences through antigenic variation. The prospects of developing vaccines to neutralizing determinants common to all strains of virus, designing vectors to maintain silent infections, and the general progress in lentivirus and AIDS research, are grounds for the hope that these problems will be resolved.

I thank my colleagues for their contributions to some of the research described in this review and for their helpful comments: Samuel Baron, Michael Bishop, Hubert Blum, Michel Brahic, Susan Carpenter, Phil Cheevers, Martin Dworkin, Anthony

Fauci, Adam Geballe, Jeffrey Harris, Colin Jordan, Jay Levy, Hal Minnigan, Opendra Narayan, Neal Nathanson, Michael Osterholm, Richard Peluso, Gudmundur Petursson, Richard Price, Ernest Retzel, Frank Rhame, Jane Scott, Katherine Staskus, Linda Stowring, Howard Temin, Betty Traynor, Lloyd Turtinen, Harold Varmus, Peter Ventura, Peter Vogt, Simon Wain-Hobson and Stephen Wietgrefe. I also thank NIH, National Multiple Sclerosis Society, American Cancer Society and Veterans Administration for support, and Jan Torma and Colleen O'Neill for preparation of the manuscript.

Pb isotope evidence in the South Atlantic for migrating ridge—hotspot interactions

B. B. Hanan, R. H. Kingsley & J-G. Schilling*

Graduate School of Oceanography, University of Rhode Island, Kingston, Rhode Island 02881, USA

Variations of Pb isotopes in basalts erupted along the Mid-Atlantic Ridge suggest that heterogeneities in the upper mantle beneath the South Atlantic are highly structured and dominated by distinct east-west channels connecting the off-ridge plumes with the westward-migrating ridge. These preferential flows are superimposed on a broad radical dispersion of the St Helena and Tristan plumes into the asthenosphere before the ridge overrode these plumes.

WE have recently discovered the presence of short-wavelength geochemical and bathymetric anomalies along the Mid-Atlantic Ridge (MAR) axis just opposite the off-ridge Tristan da Cunha, St Helena and Circe hotspots^{1,2}. We proposed that these anomalies are the result of preferential flow along sublithospheric channels which have developed between the mantle upwelling zones (hotspots) and the westward-migrating MAR since it overrode these hotspots ~80 Myr ago. The ridge in this case acts as a sink and the plume a source of mantle materials. The model was initially developed by Morgan³ for the Galapagos and the Reunion hotspots, purely on the basis of tracks left by anomalous constructional volcanism on the sea floor. The model has received support from the observation that the length of these geochemical anomalies and the magnitude of the associated residual elevation anomalies along migrating mid-ocean ridges both generally decrease as the square root of distance between these migrating ridge segments and related hotspots⁴.

In the South Atlantic, we have also noted that the large geochemical dispersion observed within these spike-like geochemical anomalies may be the result of irregular mixing along these lateral flow channels, between the plume-derived material and the large-ion lithophile element (LILE)-depleted asthenosphere. Furthermore, as the South Atlantic hotspots and the LILE-depleted asthenosphere have distinct signatures in Sr, Nd and Pb isotopic space^{5,6}, a test of the connecting flow channel model and proposed mixing can easily be made by measuring the isotopic composition of basalts derived from these regions. Distinct mixing trajectories are predicted in such isotopic space¹. This is also possible with Pb isotopic ratios alone. In this case, the mixing along the connecting channels between each of these hotspots and the LILE-depleted asthenosphere source should form distinct binary mixing arrays on two-dimensional Pb isotopic ratio diagrams, as the Tristan-Gough-Discovery hotspot(s) have Pb isotopic signatures distinct from that of St Helena and the source of typically LILE-depleted mid-ocean-ridge basalts (MORB)^{5,6} (Fig. 2b). However, no prediction can be made for the Circe mixing trend since this off-ridge hotspot has not yet been sampled. Its influence on the MAR was initially suspected on the basis of geophysical and morphological criteria only1. Note also that according to these predictions, referred to here as model 1, all binary mixing trends should converge towards the compositional range of the LILE-depleted endmember source for the area (Fig. 2b).

We report on 62 Pb isotope analyses of the same basalts previously analysed for major elements and trace element abundance ratios, such as La/Sm and Nb/Zr, which were instrumental in revealing the spike-like anomalies along the MAR in the South Atlantic (Fig. 1). The Pb isotope analyses were performed on carefully selected fresh glass chips if available; otherwise, pillow interiors were used. All of the samples were carefully hand-picked, cleaned and briefly leached with hydrochloric acid

to remove possible surface contaminants. Our results are listed in Table 1, along with some details of the analytical method. We will refer to the isotopic ratios ²⁰⁶Pb/²⁰⁴Pb, ²⁰⁷Pb/²⁰⁴Pb and ²⁰⁸Pb/²⁰⁴Pb as 6/4, 7/4 and 8/4, respectively.

Pb isotope test

For comparison with our model 1 predictions, Fig. 2a shows our actual Pb isotope results plotted on an 8/4 versus 6/4 diagram. As a first-order independent discriminant, we have divided the MAR basalts from 2°S to 47°S into four geographical populations on the basis of the La/Sm variation previously reported¹ (see Fig. 1b). These populations are: 2-12° S, including the Circe spike-like anomaly; the 12-22° S segment, including the St Helena spike-like anomaly; 22-30.75°S, an apparently 'normal' ridge segment with (chondrite-normalized) $(La/Sm)_N < 0.75$, showing a slight increase southward; and 30.75-47°S, a segment which includes the Tristan-Gough-Discovery spike-like anomaly. The exact boundaries between these four geographical populations were chosen where the (La/Sm)_N appears to reach a minimum (Fig. 1b). Using these populations, Fig. 2a shows that the St Helena-MAR population (12-22°S) follows a linear array pointing towards the field occupied by the off-ridge St Helena hotspot, and the 30.75-47° S population shows a broad cluster slightly elongated towards the field occupied by the off-ridge Tristan-Gough-Discovery hotspots. However, the 2-12°S MAR population does not form a single linear array; instead at least two linear arrays seem required by the data. The subpopulation from the 7-12° S segment comprising the Circe spike anomaly branches out from that of the St Helena array towards higher 8/4 ratios, presumably pointing towards values representing the Circe off-ridge hotspot rather than the nearby Ascension island. The Pb isotope data reinforce our previous inference^{1,4} that the influential hotspot in this region is located east rather than west of the MAR and may be beneath Circe Seamount¹. The origin of Ascension Island remains uncertain. Rather than being a hotspot itself, its formation may be related to tectonic adjustment in the region, involving MAR rift jumps and migration caused by the Circe hotspot, as well as perhaps the presence of the Ascension fracture zone In contrast, the subpopulation from 2-7°S (just north of the Circe anomaly) is among the least radiogenic Pb found in ocean-floor basalts, and is indistinguishable from that of the St Helena binary mixing array in the 8/4 versus 6/4 diagram, but, in fact, would show a higher slope on a 7/4 versus 6/4 plot (using data from Table 1). The same grouping and mixing array patterns just described in terms of 8/4 versus 6/4 would also be evident in the 8/4 versus 7/6 diagram, which includes the variation of all four isotopes of lead. On the other hand, there is more scatter and the mixing arrays are not as readily separated in the 7/4 versus 6/4 diagram, because the Tristan and apparently the Circe mantle plume sources lie closer to the

Table 1 Lead isotope ratios* in dredged basalts from the Mid-Atlantic Ridge, 2-47° S

^{*} The Pb isotopic ratios were normalized on the basis of replicate measurements of NBS SRM981, using Todt et al's values (ref. 47). Duplicate analyses are on different pieces from the same sample. The discrimination factor averaged 0.97 ± 0.06 (2 standard errors) % per mass unit. The isotopic ratios were measured at URI on a VG Micromass 30B single collector, double focusing, thermal ionization mass spectrometer. A standard ion exchange procedure was used to separate Pb prior to mass spectrometry (ref. 49).

† g in sample identification stands for glass, otherwise pillow interiors.

‡ Errors in parentheses are 2 standard errors of the last significant figures, taking into account within-run precision and the uncertainty in the discrimination correction. Ph blanks are <0.15 ng on sample sizes up to 0.5 ng and are perligible.

discrimination correction. Pb blanks are <0.15 ng on sample sizes up to 0.5 g and are negligible.

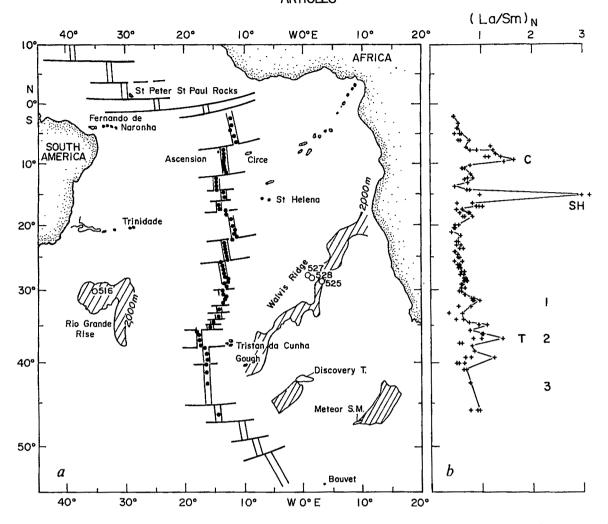

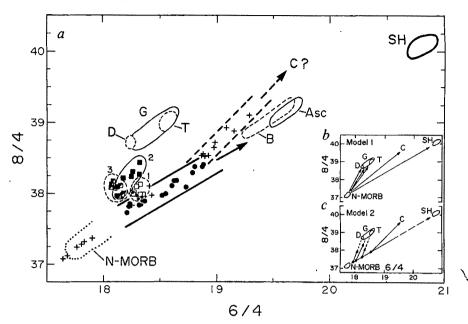

Fig. 1 a, Tectonic map of the South Atlantic showing the location of dredged basalts along the MAR, DSDP holes 525A, 528, 527 and 516F (open circles), off-ridge hotspots (islands) and their tracks (hatched areas of seamount chains). b, Corresponding latitudinal variation of chondrite-normalized La/Sm in dredged basalts from the MAR-axis. Note spike-like anomalies opposite Circe (C), St Helena (SH) and in the vicinity of the Tristan-Gough-Discovery hotspots (T). Note that there may be at least three distinct small spikes (1, 2, 3) in the latter broader anomaly. These geochemically anomalous ridge segments are also accompanied by anomalous elevation of the ridge axis (see ref. 4); they may reflect lateral sub-crustal plume flow feeding the spreading ridge axis from the corresponding off-ridge hotspots. The analytical uncertainty in the (La/Sm_N) is less than the size of the symbols.

LILE-depleted asthenosphere-St Helena binary mixing array in terms of 7/4. Overall, the mixing systematics described above are self-consistent among the different projections in Pb isotope ratio space. The three distinct arrays are also statistically recognizable in a 6/4-7/4-8/4 three-dimensional space using the method of principal component analysis. This statistical test will be discussed elsewhere (D. A. Fontignie, J.G.S. and B.B.H., in preparation).

Thus, overall, our first-order test of the hotspot sourcemigrating ridge sink and flow connection is essentially positive in the broad sense that the data indeed reveal distinct binary mixing arrays pointing towards respective fields representing the South Atlantic off-ridge hotspots. However, there are also some important differences. Notably, the three binary mixing arrays do not readily converge towards the field occupied by the LILE-depleted asthenosphere source and thus do not form the fan-tail arrangement of binary arrays initially expected (see model 1 in Fig. 2b). Instead, both the Circe binary array comprising the 7-12° S spike population and the 30.75-47° S MAR spike population tend to intersect that of the St Helena-MAR spike population at different levels of 6/4, as if the end-member LILE-depleted asthenospheric source in these regions were already isotopically polluted with a component rich in 6/4, perhaps composed of the St Helena type of material. The details

are more evident when the 30.75-47° S population is subdivided into three segments (30.75-34° S, 34°-39° S, 39°-47° S). This is done on the basis that the migrating MAR could have overridden three different hotspots in the region, Tristan, Gough and Discovery, thus producing three distinct lateral channels; also from the fact that basalts from these three hotspots indeed have distinct 6/4 (Fig. 2a); and finally that three small (La/Sm)_N spikes are also observed along the 30.75-47° S MAR segment (spikes 1, 2, 3 in Fig. 1b). Figure 2a shows that the 30.75-34° S subpopulation forms an array pointing towards the field for Tristan Island, which is geographically located closest to this segment. The southern subpopulation (39-47°S) is subparallel to the former and points towards the field of the off-ridge Discovery Tablemount, which is also closest to this segment. And finally, the MAR segment closest to Gough Island forms another subparallel array intermediate in position between the former two arrays, although overlapping significantly with the other two arrays in terms of 6/4. This is expected as the field occupied by Gough Island basalts reflects a relatively large range in 6/4 which overlaps that of Discovery Tablemount and Tristan Island (Fig. 2). The fact that the north-south zoning along the MAR in terms of 8/4 versus 6/4 space is essentially the same as for the three off-ridge hotspots, indeed, supports the possible presence of a strongly laminated east-west mantle flow pattern,

Fig. 2 8/4 versus 6/4 Pb isotope covariation diagram showing the South Atlantic MAR basalts in relation to: the field occupied by South Atlantic island basalts from off-ridge hotspots, including Discovery (D), Gough (G), Tristan (T), Bouvet (B), Ascension (Asc) and St Helena (SH) (taken from ref. 28); and the field occupied by normal MAR basalts from the North Atlantic (N-MORB) (taken from refs 16, 28, 30, 48). The island fields include analytical uncertainties. Symbols for basalts from the South Atlantic MAR segment subpopulations, based on the distribution of spike-like La/Sm anomalies shown in Fig. 1b, are: 2-12°S, including C-spike (crosses, heavy dashed-line array); 12-22° S, including SH-spike (filled circles, heavy-line array); 22-30.75° S (small dots); 30.75-34°S, including T-1 spike (open squares, thin dashed-line envelope); 34-39°S, including T-2 spike (filled squares, thin full-line envelope); and 39-47°S, including T-3 spike (half-filled squares, thin dashed-line envelope). The analytical uncertainties are less than the size of the symbols. Note: how basalts from the La/Sm spike-bearing MARsegment subpopulations tend to form distinct linear arrays pointing towards the field occupied by the geographically related off-ridge hotspots; two dis-

tinct linear arrays are required by the 2-12° S population. Geographically these correspond to segment 2-7° S (crosses overlapping with N-MORB field), which points towards St Helena or Ascension (but this is not the case on a 7/4 versus 6/4 plot; see also Fig. 5): and the 7-12° S segment (heavy dashed-line array), which points neither towards St Helena nor Ascension Island, but rather towards a field presumably occupied by the large Circe Seamount shown in Fig. 1 (8°15′ S, 9°20′ W)—presumably the influential off-ridge hotspot at this latitude. Three crosses present between these two arrays (samples EN61 8D-2, 13D-1 and 14D-1g), located on the two lower flanks of the C-spike of Fig. 1b, do not readily fit either of these two arrays (see also Fig. 5). b, Idealized binary mixing model 1 initially expected to account for the spike-like geochemical anomalies shown in Fig. 1b. Basalts from each spike would form a vector representing binary mixing between a pure, LILE-depleted, asthenosphere end-member source and plume material of Pb isotope composition characteristic of the off-ridge hotspot sources present at the corresponding latitude of these MAR spikes. c, Idealized binary mixing model 2, reflecting a possible interpretation of the Pb isotope distribution actually observed and shown in a. Distinct binary-mixing vectors are preserved between the off-ridge plumes and a LILE-depleted end-member which is no longer constant in accomposition, but is polluted (enriched) to various extents with a St Helena-plume-type end-member material whose contribution increases southward along the MAR. Presumably, the broad background pollution of the LILE-depleted source would have taken place before the migrating MAR sink passed over this hotspot. Black dots at the intersection of the binary mixing vectors D, G and T with the SH-LILE-depleted asthenosphere binary would give the Pb isotope composition of the polluted LILE-depleted asthenosphere at the latitudes of the C, SH and T(-1, -2, -3) geochemical anomalies shown in Fig. 1.

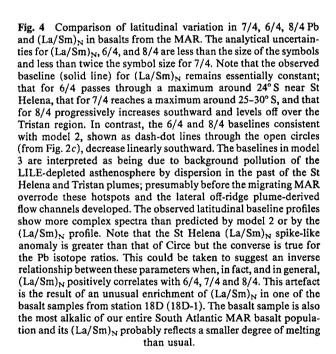

or distinct channels along which binary mixing is predominant, but the LILE-depleted asthenosphere source end-member entering the binary mixture is apparently itself already polluted with a 6/4-rich component (such as St Helena-type material). The influence of this 6/4-rich pollutant apparently decreases southward in some systematic way. An idealized sketch of such an updated mixing model is illustrated in Fig. 2c, where it is referred to as model 2. In this idealization, the pollutant of the LILE-depleted asthenosphere would be of the St Helena type only.

In terms of Pb isotope space, it appears that the MAR basalt variation within the Circe-related spike (2-12°S) and the Tristan-Gough-Discovery-related spike (30.75-47° S) may represent mixtures of at least three pure end-member isotopic components, whereas the St Helena-related spike (12-22°S) is dominantly a mix of only two pure end-member components. Physically, however, the Pb isotope data do not contradict the possibility that along each of the proposed lateral channels and beneath the MAR, the mixing would have taken place between only two types of material, as initially proposed; that is, the surrounding asthenosphere polluted to various extents (depending on the region) and the mantle plume material derived from each of the South Atlantic off-ridge hotspots. An important question which pertains to constraining or deciphering the overall dynamics of the mantle beneath the South Atlantic, is to establish more closely the nature of the background pollutant and map its possible geographical distribution. Is it random? Or does it bear some kind of a relationship with the location of St Helena or some other hotspot? Or, for instance, how does it relate to the so-called DUPAL¹⁰ anomaly? If random, the pollution could, for example, be the result of minor addition of metasomatic fluids, whereas if it bears some relation to the location of St Helena it could be related to the dispersion of this mantle plume into the surrounding athenosphere by convection¹¹⁻¹⁵. Insight may also be gained into the mantle flow pattern with depth by comparing our MAR profile with the semi-hemispherical DUPAL anomaly revealed from isotope systematics of ocean island volcanism¹⁰, as it is generally thought that MORBs are sampling a rather shallow upper mantle, whereas ocean island volcanism seems to tap deeper sources.

Asthenosphere pollution

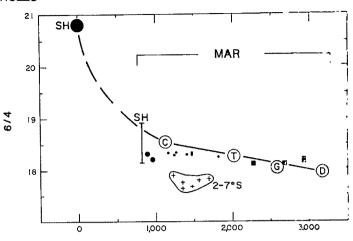

First, we will briefly pursue the consequences of our updated idealized model 2 in Fig. 2c. The intersections of the four binary mixing arrays formed by the MAR anomalies associated with Circe, Tristan, Gough and Discovery with the St Helena-LILEdepleted asthenosphere binary, would provide essentially the mean Pb isotopic value of the polluted asthenosphere endmember present beneath the MAR near the intersection with each of the four proposed connecting channels. Remarkably, Fig. 3 shows that these mean values are inversely related to radial distance from the St Helena hotspot, which would suggest that the extent of pollution of the asthenosphere is related to the St Helena plume location and may be a reflection of its broad dispersion into the upper mantle by convection. Thus, although a significant portion of the plume has been deflected along the connecting lateral channel since the migrating MAR overrode this hotspot, the remaining fraction may at the same time and to a lesser extent have been distributed radially into the upper mantle. The radial dispersion could also have taken place earlier, when the ascending plume was totally intraplate

Fig. 3 Plot of 6/4 Pb isotopic composition of the hypothetical model 2, LILE-depleted, St Helena-polluted, asthenosphere present beneath the MAR axis at the latitude of the C, SH and T-1, T-2 and T-3 spike-like anomalies shown in Fig. 1 (intersections of the migrating MAR axis with the lateral flow channels from offridge plumes located east of the ridge), as a function of radial distance from St Helena hotspot to these intersections. The uncertainties are of the order of the size of the surrounding circles. See Fig. 2c for method used in determining these hypothetical endmember Pb isotopic compositions (dots). The apparent negative correlation suggests that the extent of pollution of the LILEdepleted asthenosphere about the St Helena hotspot, by dispersion, may have been radial in the past (before the migrating MAR axis overrode the St Helena hotspot). Also superimposed is the Pb isotopic variation of basalts with normal ridge segments (that is (La/Sm)_N<0.63 in Fig. 1b). N-MORBs from segments 12.5-14.5°S (large dots); 20.5-30.75°S (small dots), 34.6-40.4°S (squares) tend to follow the negative correlation, but segment 2-7°S is clearly not related by radial dispersion-pollution model 2, suggesting additional complications.

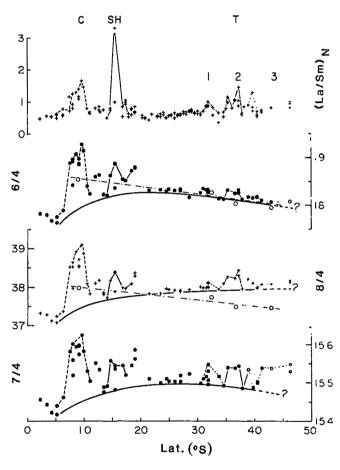

and spread on encountering the rigid lithosphere above. Alternatively, the radial dispersion or pollution could reflect a redistribution due to secondary cellular convection in the upper mantle in the region¹¹⁻¹⁵.

We can further test the radial distribution pattern of the pollutant suggested by our model 2 interpretation in two ways. First, we superimpose in Fig. 3 the Pb isotope variations actually observed along the ridge segments located in between those that contain the $(La/Sm)_N$ spike-like anomalies; that is: the segments from 2-7° S, 12.5-14.5° S, 20.5-30.75° S and 34-35° S. On the basis of the $(La/Sm)_N$ variations, these segments would appear to be essentially 'normal' and unaffected by plumes (that is $(La/Sm)_N < 0.63$ and normal ridge elevation). The Pb isotopic vairation along these segments with respect to radial distance from St Helena should follow the same pattern as predicted by our new model 2 interpretation. Figure 3 shows that the match

Radial distance to St Helena (km)

is generally poor, particularly for the 2-7°S and 12.5-13.5°S segments, suggesting additional complications or some inconsistencies in interpretation. The second test is made by comparing, on one hand, the (La/Sm)N and Pb isotopic profiles along the MAR and, on the other, the 6/4 and 8/4 Pb isotopic baselines observed with those suggested by contamination model 2 (Fig. 4). Between the Circe, St Helena and Tristan-Gough-Discovery spike-like anomalies, the (La/Sm), ratio returns to a baseline value that would be considered as typical of normal ridge segments in the North Atlantic or Pacific. In contrast, the baselines for the three Pb isotope ratios do not stay constant. The baseline for 6/4 goes through a maximum around 24°S, and that of 7/4 perhaps around 25-30 °S, whereas the baseline for 8/4 keeps increasing southward and tends to level off over the Tristan Platform transect. In contrast to these observations, the model 2 interpretation indicates that the 6/4 and 8/4

baselines should decrease linearly southward. The latitudinal Pb isotope ratio profiles thus show more complex spectra than predicted by model 2 or by the (La/Sm)_N profile, with spikes at the latitude of the hotspots as for the (La/Sm)_N (resulting from the channelling of the plumes), superimposed on a broader background variation related to dispersion into and pollution of the asthenosphere, perhaps by two rather than a single hotspot. We will refer to the two-background-pollutant model as model 3. Two major background pollutants of the asthenosphere are apparent from the following reasoning. First, the component rich in 6/4 reaches a maximum near 24°S close to St Helena Island, which suggests that its source may indeed be St Helena. On the other hand, the background pollutant component rich in 7/4 and 8/4, which seems to reach a maximum further south in the vicinity of the Tristan-Gough-Discovery hotspots, may be related to this group of hotspots, since these hotspots are also characterized by high 7/4 and 8/4 but relatively low 6/4 (Fig. 2). Such an 8/4- and 7/4-rich pollutant of the asthenosphere has also been observed in the Indian Ocean and has been attributed to pollution by a hotspot with Kerguelen-type Pb (refs 16-20).

The details of the two-component pollution of the asthenosphere source in the South Atlantic (model 3) is best revealed by studying the relative Pb isotopic variation (6/4, 7/4, 8/4) in a triangular diagram, using first only basalts with (La/Sm)_N< 0.63. These MAR basalts lie outside the three noted (La/Sm)_N spikes and usually would be considered as derived from the so-called LILE-depleted asthenosphere. The location of the transition zone where the St Helena type of pollutant fades out and the Tristan type becomes more dominant, is readily detectable in such a triangular diagram²¹ (Fig. 5a). From 2° S to 24° S the mixing line is essentially binary between the LILE-depleted source and the St Helena type of pollutant, the latter increasing fairly systematically southward to reach a maximum at 24° S. where the St Helena-type pollutant is felt most (see sequence along this trend). South of 24°S, the trend becomes ternary, with the influence of the Tristan-type pollutant becoming progressively more important and the St Helena type decreasing southward, while the 207Pb-rich component characterizing the N-MORB's source stays constant. Further south the trend systematically reverses, as the pollutants from both Tristan and St Helena decrease southward and the contribution from the N-MORB's source increases slightly. Note that the 24-47° S population overlaps the field found for the so-called normal MORBs from the three Mid-Indian-Ocean Ridges 16-20. Finally, we note that had the Tristan-type pollutant south of 24° S along the MAR not been present, the trend would have shown a reversal of the sequence along the same St Helena-asthenosphere mixing trend. The systematics observed with respect to the St Helena and Tristan hotspot locations is thus remarkably clear on such a triangular diagram (Fig. 5).

In comparison, MAR basalts located within the anomalous spikes depart from this sequence and form mixing-vector-like trends, which again tend to be directed towards the fields occupied by their respective plume end-members (Fig. 5b). The exact proportions of the two types of plume pollutants in the asthenosphere beneath the MAR sampling profile, or the mixing proportion within the spikes, cannot be more quantitatively described, as this would require knowing the Pb concentration in such plumes which are unknown and which need not be the same. There is also no guarantee that the Pb isotopic composition of the sources of the island basalts are representative of the pure end-member plumes. In fact, the vector-like trend formed by Tristan-Gough Islands and Discovery Tablemount themselves (Fig. 5b) suggests both a progressive southward increase in the LILE-depleted asthenospheric component (relatively rich in ²⁰⁷Pb) and a progressive decrease in the ²⁰⁶Pb-rich St Helenatype pollutant with increasing distance from St Helena Island. Thus, the extent of pollution of the asthenosphere by the St Helena-derived pollutant appears to be spatially widespread

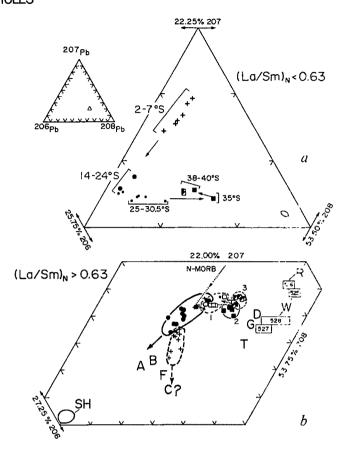

beneath the South Atlantic. It may have partly diluted neighbouring plumes as well, and the pollution may have taken place for quite some time. In fact, the spatial southward decrease in 6/4 pollution is also observable in the past, across the Walvis Ridge, from basalts recovered from the north-south DSDP drill hole sequence 527, 528, 525 (ref. 22) (Figs 2a and 5b). According to the fixed hotspot reference frame²³, these basalts were also erupted beneath the Tristan hotspot and slightly northward.

Finally, there is also a suggestion of a temporal increase of the St Helena pollutant with time from the vector-like sequence exhibited in Fig. 5b by lavas from the Rio Grande Rise, Walvis Ridge, Discovery Tablemount, Gough and Tristan da Cunha. For example, basalts from the Rio Grande Rise (produced at the Tristan Hotspot, 86 Myr ago; ref. 24), followed by Walvis Ridge basalts (69-71 Myr; ref. 25), are progressively less polluted in 6/4 relative to modern basalts from Tristan Island $(<10^5 \text{ yr}; \text{ ref. 26})$. In this time versus extent of 6/4 pollution sequence, the Discovery basalt (25 Myr old; ref. 27) comes third, and Gough, fourth (2-6 Myr; ref. 26), although in this case the radial distance from these two hotspots to St Helena is greater than from Tristan. A more detailed scrutiny of temporal and spatial relationships is not warranted here, as some of these basalts need first to be age-corrected for radiogenic Pb buildup since erupted (once parent/daughter concentrations become available).

Mantle dynamics beneath the South Atlantic

The concept of pollution of the LILE-depleted asthenosphere by the random disperson of blobs by convection as they ascend through the asthenosphere, was first suggested by Allègre and co-workers^{15,17-19}. Their arguments are based on a rather coarse sampling of the mid-ocean ridge system in the Atlantic, East Pacific and Indian Oceans at ~100-500 km intervals. Their comparative study shows that the pollutant in the Indian Ocean appears generally to be rich in 8/4 (Kerguelen or Tristan type) relative to the North Atlantic or East Pacific where such a pollutant has not been observed, but instead a pollutant rich in 6/4, similar to St Helena type, may be present and responsible for the elongation of the MORB field in the 7/4 versus 6/4 diagram²⁸⁻³². These observations have led Allègre and coworkers to suggest the blob cluster model, or provinciality of blob types^{15,17-19}. In contrast, our more detailed sampling (30-100 km intervals) of the North Atlantic³³ the Galangoos³⁴⁻³⁶ 100 km intervals) of the North Atlantic³³, the Galapagos and now the South Atlantic^{1,2}, has led us to pursue the more deterministic, fixed plume source-migrating ridge model^{1,3,37}. The Pb isotope evidence presented for the South Atlantic lends some support to both models and helps merge the two models towards describing a more realistic picture of upper-mantle dynamics. Our results show that heterogeneities in the upper mantle beneath the South Atlantic are not randomly distributed. but highly structured and dominated by east-west laminations, with streaks of identifiable isotopic signature corresponding to that of the hotspots located approximately at these latitudes east of the MAR. Thus, the probable existence of lateral sublithospheric channels, or tongues, connecting these off-ridge plumes and the westward migrating MAR at shallow depth in the upper mantle is substantiated by our Pb isotope test. An important fraction of the present plume flow around these hotspots is apparently strongly skewed along these distinct channels, which may have developed since the migrating MAR ridge sink has overridden the plumes. Mixing of plume-derived material with the asthenosphere along these channels appears irregular and apparently not purely binary as initially thought on the basis of trace element abundance ratios only, with the possible exception of the MAR-St Helena channel. The depleted asthenosphere beneath the South Atlantic appears to have also been broadly polluted by at least two distinct components, one of the St Helena type, the other of the Tristan type. The degree of pollution is apparently directly related to distance to these hotspots. The St Helena-related pollutant seems to be more

Fig. 5 Triangular plot of relative abundances of Pb 206, 207 and 208 in MAR basalts from the South Atlantic. a, With (La/Sm)_N< 0.63 (only N-MORB). Note that N-MORBs from the 2-24° S ridge segment suggest an array which reflects dominantly binary mixing between the LILE-depleted asthenosphere and the St Helena-type plume source (rich in 206Pb), with St Helena's contribution to the mix increasing southward (a pollution model of the asthenosphere dominated by St Helena). In contrast, N-MORBs from segment 25-35° S reflect ternary mixing between the LILE-depleted asthenosphere, St Helena and Tristan (rich in ²⁰⁸Pb) plume-type sources of pollutants, with Tristan's contribution to the mix increasing southward to the detriment of St Helena's, whereas the LILEdepleted source's contribution stays essentially constant. Southward, past Tristan, N-MORBs from segment 38-40°S are still reflecting ternary mixing, but with both St Helena and Tristan's types of pollutants of the LILE-depleted asthenosphere now decreasing southward. The analytical uncertainties are given by the error polygon in the lower right corner of the plot. b, With (La/Sm)_N>0.63 (basalts from the C, SH, and T-1, T-2, T-3 spike highs shown in Fig. 1b). Also plotted are averages of basalts from relevant South Atlantic off-ridge hotspots, and range for basalts from DSDP holes 525A, 527 and 528 on the Walvis Ridge (W) and 516F on the Rio-Grande Rise (R) (data uncorrected for age); and for reference, the N-MORB trend of Fig. 5a (dotted line). Note how the SH spike points towards the St Helena island field, the T-1, 2, 3 spikes towards Tristan-Gough-Discovery off-ridge hotspot fields, and the C-spike towards values corresponding neither to Fernando De Noronha (F), Bouvet (B), nor Ascension (A), but presumably Circe seamount (C). Note also that the three odd basalts discussed in Fig. 2 are part of the ternary mixing for N-MORBS discussed in a, and that the off-ridge Tristan (T), Gough (G) and Discovery (D) hotspots are progressively less enriched in the St Helena, ²⁰⁶Pb-rich, pollutant, moving radially southward from St Helena Island. See text for discussion of DSDP holes. Symbols used are the same as defined in Fig. 2.

widespread and to have polluted the plumes ascending, apparently at a rate increasing with time, towards the south within the past 80 Myr.

These observations are not unexpected within the framework of the migrating ridge sink-plume source model, which includes three critical stages of plume dispersion into the asthenosphere: (1) intraplate, when dispersion was at a maximum: (2) ridge-centred, when dispersion was at a minimum; and (3) off-ridge-channel-connected, when dispersion is intermediate^{1,4}. According to plate reconstruction models^{23,38,39}, the time-spans for these three stages for St Helena are respectively 75-90, 0-15 and 110 Myr, whereas for Tristan these are 60, 20-40 and 60-80 Myr. Thus, for comparable plume size or flux, the radial dispersion of the St Helena plume is expected to be more widespread than for the Tristan plume.

Within the frameworks of both the blob cluster model¹⁵ and the DUPAL anomaly10, one could conclude that the MAR region between 24 and 35°S marks the transitional boundary between the 8/4 Pb-rich, Kerguelen-Tristan blob cluster which dominates the Indian Ocean, and the 6/4 Pb-rich St Helena blob cluster which dominates the Atlantic, north of this boundary. However, in detail the pattern of pollution and dispersion is more complicated, apparently of smaller scale and tied to local hotspots. Sampling of the mid-ocean ridge system in the vicinity of the Bouvet triple junction suggests that the influence of the Bouvet plume, whose Pb isotope signature is intermediate between the Tristan-Kerguelen and the St Helena type (Figs 2a and 5b), can be detected and seems to extend irregularly over ~300-1,700 km along the three plate boundaries branching from the triple junction⁴⁰⁻⁴². Further north, we have seen that the extent of asthenosphere pollution, and the geochemical nature of the pollutants along the mid-ocean ridge system, are closely tied to the types of plume present in their vicinity. This tends to rule out a background pollution of the asthenosphere beneath the region by random addition of LILE-rich metasomatic fluids migrating from deeper zones of the Earth's mantle. Instead, the background pollution observed is more likely to reflect the dispersion at shallow depths of the South Atlantic plumes. However, the mechanism of dispersion of these plumes (or vertical chains of blobs) remains uncertain. It could be the result of a complex mantle convection pattern in the asthenosphere (see refs 11-15). Or, the dispersion could simply be the result of a radial flow of the plumes discharging into the asthenosphere, particularly when they were totally intraplate and had not yet sensed the effect of the spreading ridge axis (the sink). Or for that matter, both mechanisms may well have been operative⁴³. Our isotopic data does not allow such distinction.

Finally, we consider the observation that the Pb isotopic ratios seem to be more sensitive than the La/Sm or Nb/Zr ratios at detecting the broad background plume-related pollutant along the so-called normal ridge segments, as illustrated by the discrepancies in the baselines shown in Fig. 4. A proper understanding of such discrepancy, which at first may appear paradoxical, is important as it pertains to constraining not only the trace element and isotopic ratios, but also the elemental concentrations in the various plumes relative to that of the LILE-depleted asthenosphere, particularly of the elements in the denominator of these trace element or isotope ratios. In turn, this should help in constraining, or even mapping, the relative mass distribution of the different pollutants affecting the asthenosphere, and help understanding the mechanisms of dispersion heterogeneities and mantle dynamics in general. Two factors may contribute to the different sensitivities in detecting asthenosphere pollutants. One stems from mixing, the other from partial melting. First, it should be recalled that in mixing two reservoirs with distinct trace element or isotope ratios, the ratio in the

mixture is usually not linearly related to the mass-fraction entering the mix, unless the concentration ratio 'n' between the plume source (pollutant) and the asthenosphere source, of the chemical species in the denominator of such trace element or isotope ratios is unity^{44,45}. The parameter 'n' controls the curvature of the hyperbolic mixing curves. The greater is 'n', the more readily can a small fraction of the pollutant entering the mixture be detected. Since Pb isotopic ratios are more sensitive in revealing the plume pollutants in the South Atlantic than the (La/Sm)_N ratio (or the Nb/Zr analogue¹), it suggests that 'n' for Pb is greater than for Sm or Zr. In other words, Pb appears to be more incompatible than Sm or Zr. This is apparently also the case around Iceland²⁹, where 'n' for basalts derived from the Iceland plume relative to those derived from the LILE-depleted source south of 60° N is ~4 for Pb but only 1.5 for Sm (ref. 46). Although the ratio 'n' measured in the basalts is not necessarily identical to the ratio in the sources of these basalts, as it is affected by operative degrees of partial melting beneath Iceland and south of 60° N, the relative variation of 'n' among various trace elements is helpful.

Another mechanism suggested by G. Waggoner (personal communication) may be invoked if the plume-derived dispersed heterogeneities (pollutant) affecting the LILE-depleted source beneath the MAR have suffered some melt extraction in the recent past, but before the final partial melting stage taking place directly beneath the MAR axis. If this were the case, incompatible elements which partition preferentially into such melts would also be preferentially removed, thus generating residual plume material (plumes being dispersed towards the ridge) with lower ratios of highly incompatible to moderately incompatible elements (such as La/Sm or Nb/Zr). These residual plumes would thus have intermediate trace element ratios between that of the original plume and the LILE-depleted asthenosphere. In contrast, these dispersed residual plumes would still have a Pb isotope composition similar to that of the original plume even after a 100-200 Myr residence time in the asthenosphere, because of the long half-lives of the radioactive parents U and Th. The more different the trace element or

isotope ratio of the plume-derived pollutant is from that of the LILE-depleted asthenosphere, the more readily can it be detected in the mixture sampled along the MAR, even if the ratio 'n' discussed earlier is unity. The plausibility of this mechanism for the South Atlantic will depend on knowing better the dynamics and thermal structure of the upper mantle, to determine over what depth range the dispersion of these plumes and partial melting may take place. The question also requires a detailed analysis of relative rates, including the ridge migration and horizontal velocities of the plume domains being dispersed both along the proposed channels and radially.

Although the origin of mantle heterogeneities and mechanism of dispersion in the upper mantle remains an open question, we believe that some of the major discrepancies remaining between the different models discussed here may be more a reflection of the different scales of sampling existing along the mid-ocean ridges, rather than being of real substance. The evidence for upper mantle flow lamination in the South Atlantic would probably not have been detected had a sampling at intervals of 100-500 km been used, as currently available in the Indian Ocean¹⁶⁻²⁰. Morgan³ initially developed the model of plume source-migrating ridge sink and connecting channel on the basis of the track of constructional volcanism on the sea floor between the Reunion hotspot and the eastward-migrating Central Indian mid-ocean ridge. It would be of great interest to find out if a denser sampling of the region might reveal, in addition to the general background Kerguelen-Tristan pollutant already observed 16-20, some well-defined, spike-like geochemical anomalies along this ridge opposite the Reunion hotspot, as well as opposite other hotspots in the Indian Ocean, as our model predicts and sparse existing data already suggest^{18,19}

The sampling and initial stage of this study was done in collaboration with G. Thompson and S. Humphris (WHOI). Samples from Cruise EN63 were provided by H. Sigurdsson (URI). We also benefited from fruitful discussions with G. Waggoner and M. Cole. Assistance from S. Benson, B. McCully and the staff at RINSC are appreciated. This work was supported by the NSF.

Framework monoclonal antibodies have identified a population of human lymphocytes that express the T3 glycoprotein but not the T-cell receptor (TCR) α - and β -subunits. Chemical crosslinking experiments reveal that these lymphocytes express novel T3-associated polypeptides, one of which appears to be the product of the Ty gene. The other polypeptide may represent a fourth TCR subunit, designated To.

UNDERSTANDING T-cell recognition of antigen and the restriction of this process by major histocompatibility complex (MHC)encoded antigens has been an important goal in immunology. A major step forward occurred with the immunochemical identification of clone-specific disulphide-linked heterodimers on T cells, composed of subunits termed TCR α and β (relative molecular mass (M_r) 50,000 (50K) and 40K, respectively)¹⁻³. Genes that rearrange during thymic ontogeny and encode the TCR $\beta^{4,5}$ and α^{6-8} subunits were isolated either by subtractive hybridization or by probing with oligonucleotides.

A unique feature of the human TCR $\alpha\beta$ was the observed co-modulation², co-immunoprecipitation^{9,10} and required coexpression¹¹ of the TCR $\alpha\beta$ molecules with the T3 glycoprotein, which suggested that these two structures were related. Subsequently, the direct physical association of the two protein complexes was demonstrated by chemically crosslinking the TCR $\alpha\beta$ molecules to the T3 glycoprotein and identifying the components of the crosslinked complex as the TCR β -subunit and the T3 glycoprotein 28K subunit¹². A T3 counterpart is similarly associated with murine TCR $\alpha\beta^{13,14}$.

A third gene that rearranges in T cells, designated $T\gamma$, has been identified in mouse¹⁵⁻¹⁷ and man^{18,19}. Ty gene rearrangements occur in lymphocytes with suppressor-cytotoxic as well as helper phenotypes and may produce a large number of $T\gamma$ chains 18-23. However, the function of the $T\gamma$ gene is unknown. Furthermore, neither the protein encoded by the Ty gene nor its possible association with other structures (as occurs with TCR $\alpha\beta$ and T3 glycoproteins) has been defined.

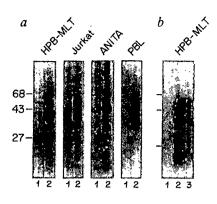

It appears increasingly likely that the TCR $\alpha\beta$ molecule alone determines both antigen recognition and MHC restriction on at least some T cells^{24,25}. However, it is unclear whether this receptor accounts for the process of T-cell selection during thymic ontogeny or for all antigen-specific recognition by mature T cells. For example, suppressor T lymphocytes remain an enigma; in some cases they delete or fail to rearrange TCR β genes^{26,27}. Thus, it is of great importance to determine whether a second T-cell receptor exists, to define its structure (particularly with regard to the possible use of the $T\gamma$ gene product) and ultimately to understand its function(s).

Here, framework monoclonal antibodies that react with shared determinants on human TCR $\alpha\beta$ molecules were used to identify peripheral blood lymphocytes (PBL) that were T3⁺ but did not react wth these monoclonal antibodies. We reasoned that such lymphocytes might express non- α , non- β T3-associated structures and that such molecules might represent a second T-cell receptor complex. This strategy resulted in the identification of a T3-associated molecular complex on the surface of human lymphocytes that do not express detectable TCR a and β transcripts or polypeptides. We suggest that this complex is a putative second T-cell receptor.

Monoclonal antibodies

A murine framework antiserum that recognizes most human TCR $\alpha\beta$ molecules has been reported previously²⁸. Subsequently, a murine monoclonal antibody, called β Framework 1 (β F1), that is reactive with shared determinants on the human TCR β -chain was obtained (M.B.B. et al., in preparation). The βF1 antibody reacts with most T3⁺ human PBL and is capable of immunoprecipitating the TCR $\alpha\beta$ heterodimer from all human T-cell lines examined that have $\alpha\beta$ T-cell receptors and express the T3 glycoprotein. Immunoprecipitations from a panel of T-cell lines using β F1 demonstrate this reactivity as well as the heterogeneity of the TCR α - and β -subunits from different receptors (Fig. 1a). Like the framework antiserum²⁸, this monoclonal antibody does not stain the surface of living T cells, but will react specifically with both membrane and cytoplasmic T-cell receptors after partial solubilization of the lymphocyte plasma membrane with 70% ethanol. Double staining of human PBL with fluorescein-conjugated anti-T3 monoclonal antibody and biotinyl- β F1 monoclonal antibody, followed by phycoerythrin-conjugated avidin reveals that β F1 recognizes 95-97% of peripheral blood T3⁺ lymphocytes. However, it clearly defines a small population of T lymphocytes that is $\beta F1^-$, yet $T3^+$ (Fig. 1c).

A second framework monoclonal antibody, WT31, initially thought to recognize the T3 antigen²⁹, has recently been shown to react with a common epitope of human TCR $\alpha\beta^{36}$. While double staining with anti-T3 monoclonal antibody (OKT3) and WT31 revealed that each antibody blocks binding of the other, one-colour fluorescence indicated that WT31 typically recognizes 1-3% fewer cells in peripheral blood than does anti-T3 (data not shown). WT31 efficiently binds to the surface of T cells (for example, in fluorescence-activated cell sorter (FACS) analyses) and is capable of immunoprecipitating the TCR $\alpha\beta$ molecules, albeit inefficiently, from radiolabelled detergent lysates³⁰ (see also Fig. 1b, lane 3). Thus, β F1 and WT31 appear to recognize all but a small fraction of human peripheral blood T3⁺ cells, and define a subpopulation that is T3⁺ but unreactive

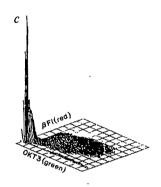

Fig. 1 Reactivity of framework monoclonal antibodies recognizing TCR $\alpha\beta$. a, Immunoprecipitates from 125 I-labelled lymphocyte lysates were analysed by SDS-PAGE. The radioiodinated T-cell leukaemia lines HPB-MLT and Jurkat, the human T-lymphotropic virus type 1-transformed cell line ANITA and resting PBL were solubilized in 1% Triton X-100 and immunoprecipitated with a control antibody, normal mouse serum (NMS) (lane 1 for each cell line) or framework antibody to TCR $\alpha\beta$, antibody β F1 (lane 2 for each cell line). b, ¹²⁵I-labelled lymphocytes were solubilized in 0.1% Triton X-100 and immunoprecipitated with NMS (lane 1), anti-T3 antibody, UCHT-1 (ref. 40) (lane 2) or framework antibody to TCR $\alpha\beta$, WT31 (lane 3). The efficiency of immunoprecipitation with WT31 was improved at the lower concentration of Triton X-100 used here. c, Two-colour FACS analysis of normal adult PBL using anti-TCR $\alpha\beta$ and anti-T3 monoclonal antibodies. PBL were stained first with FITC-conjugated anti-T3 antibody (OKT3) and then with biotinyl-anti-TCR $\alpha\beta$ antibody (βF1) followed by phycoerythrin-conjugated avidin (PE-avidin, Becton Dickinson). Red and green fluorescence were measured in comparison with nonspecific control FITC- and biotin-conjugated monoclonal antibodies (data not shown). Cells unreactive with either antibody are non-T cells (lower left corner); cells that are doubly positive, reacting with both OKT3 and β F1, make up the large population of lymphocytes in the centre of the grid; cells that are \$\beta F1^{-}\$ but OKT3⁺ comprise the narrow group of lymphocytes (4% of the T3+ cells) observed along the x-axis.

Methods. Viable lymphocytes were isolated by Ficoll-Hypaque density gradient centrifugation for both SDS-PAGE and FACS analyses. For SDS-PAGE, lymphocytes were radioiodinated by the lactoperoxidase technique, solubilized in 1% Triton X-100 and immunoprecipitated using 1 µg of specific antibody (\$\beta F1\$ or UCHT-1) or 1 µl of NMS. Monoclonal antibody 187-1 (3 µg) was used as a second antibody for β F1 and UCHT-1 (ref. 47). The immunoprecipitates were then analysed by SDS (10.5%)-PAGE under reducing conditions. The ¹²⁵I-labelled molecules were visualized by autoradiography as described previously28. Two-colour cytofluorographic analysis was performed by first staining PBL with FITC-OKT3 for 45 min at 4 °C. After washing, the lymphocytes were fixed in 1% paraformaldehyde for 15 min at 23 °C and then incubated in 70% ethanol in phosphate-buffered saline (PBS) for 5 min at -20 °C. After further washing, the cells were stained with biotinyl-\$\beta\$F1 followed by PE-avidin. Analysis was performed on an Ortho cytofluorograph.

Table 1 Phenotypes of cell lines derived from PBL of immunodeficiency patients

			% Positive for:					
Cell line	Source	Description	WT31	T3	T4	T8		
1	IDP1	Allo	50	100	11	50		
2	IDP1	WT31 ⁺ sort	100	100	70	28		
3	IDP1	WT31 ⁻ sort	0	100	0	62		
4	IDP2	Fresh PBL	61	63	38	16		
5	IDP2	PHA	100	96	18	80		
6	IDP2	Allo	2	100	0	43		
7	IDP2	PHA	. 12	93	1	18		

The description of each cell line indicates either the conditions for activation of the lymphocytes, or their source. Alloantigen (allo)-activated cultures were stimulated with irradiated allogeneic PBL at weekly intervals. Mitogen (phytohaemagglutin, PHA)-activated lines were stimulated with a 1:1,000 dilution of PHA (Difco) at culture initiation. WT31⁺ and WT31⁻ sorted cell lines 2 and 3 (sort) were obtained from IDP1 cell line 1 by cell sorting analysis. All cell lines were propagated in vitro in media composed of RPMI 1640, 10% human serum and conditioned media containing 2-5 units of IL-2 as described previously³⁴. Viable lymphocytes were isolated by Ficoll-Hypaque density gradient centrifugation and stained with 0.5 µg of WT31, OKT3, OKT4 or OKT8 (Ortho, Raritan, New Jersey) for 30 min at 4 °C. After washing, the cell pellets were stained again with fluorescein isothiocyanate (FITC)-conjugated goat anti-mouse F(ab')2 fragments. FACS analyses were performed on an Ortho cytofluorograph or a Coulter Epics as described previously³⁷. Specifically stained positive cells were determined relative to a negative control profile for each cell line (stained with nonspecific control monoclonal P3X63Ag8). Cells having fluorescence intensity channel numbers greater than the intercept of the negative control profile with the baseline were counted as positive, and the per cent positive was calculated relative to the total number of cells counted.

with both of these framework monoclonal antibodies against the TCR $\alpha\beta$ molecules. Evidence that the T3⁺ lymphocytes that are unreactive with β F1 are also unreactive with WT31 is presented below. We have used WT31 primarily for FACS analyses and β F1 primarily for immunoprecipitation studies.

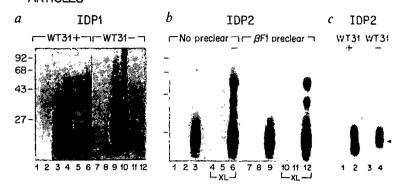

Isolation of WT31⁻T3⁺ lymphocytes

Efforts at growing the WT31⁻T3⁺ population from normal adult PBL proved difficult, as the WT31⁺T3⁺ lymphocytes usually overgrew the WT31⁻T3⁺ cells after mitogenic stimulation. However, growth of the WT31⁻T3⁺ population from the PBL of immunodeficiency patients was successful. Immunodeficiency patient 1 (IDP1) suffered from the bare lymphocyte syndrome, and lacked class II MHC antigen expression on lymphoid cells^{31,32}, while immunodeficiency patient 2 (IDP2) suffered from an ectodermal dysplasia syndrome³³ and displayed poor *in vitro* T-cell proliferative responses to mitogens.

After activation of PBL from IDP1 with alloantigen and propagation in conditioned media containing interleukin-2 (IL-2)³⁴, the resultant cell line was observed to be ~50% WT31⁺T3⁺ and 50% WT31⁻T3⁺ (Table 1, cell line 1). Subsequent sorting of this cell line yielded homogeneous populations of WT31⁺T3⁺ cells and WT31⁻T3⁺ cells (Table 1, cell lines 2 and 3, respectively).

Cell lines were also obtained from IDP2; 63% of the PBL from IDP2 were T3⁺ and 1-3% fewer cells (61%) were WT31⁺, which is typical of normal PBL (Table 1, cell line 4). Activation of these IDP2 PBL with either phytohaemagglutinin (PHA) or alloantigen and propagation in vitro with conditioned media resulted in several cell lines, including a homogeneous WT31⁺T3⁺ cell line (Table 1, cell line 5), a homogeneous WT31⁻T3⁺ cell line (cell line 6) and, on a third occasion, a cell line that was 88% WT31⁻T3⁺ (with 12% contaminating WT31⁺T3⁺ cells) (cell line 7). Note that the WT31⁻T3⁺ popula-

Fig. 2 SDS-PAGE of cell surface T3 and T3-associated (crosslinked) molecules from IDP1 and IDP2 cell lines. a, IDP1 cell lines 2 (WT31⁺) and 3 (WT31⁻) were ¹²⁵Ilabelled as described in Fig. 1 legend. Radioiodinated, intact lymphocytes were then either crosslinked by incubation in PBS (pH 8) containing 50 µg ml⁻¹ DSP (evennumbered lanes) or mock-incubated (odd-numbered lanes). The cells were then solubilized in 1% Triton X-100 and immunoprecipitated as described previously¹². Lanes 1, 2, 7 and 8 were immunoprecipitated with NMS. Lanes 3, 4, 9 and 10 were anti-T3 immunoprecipitates using UCHT-1. Lanes 5, 6, 11 and 12 were anti-TCR $\alpha\beta$ immunoprecipitates using β F1. Note that T3-associated molecules (40-55K) on the anti-T3 immunoprecipitations were detected at higher levels in the crosslinked samples than in the non-crosslinked samples. b, IDP2 cell line 7

(88% WT31⁻T3⁺) was ¹²⁵I-labelled and either treated with DSP [crosslinked samples (XL) lanes 4-6 and 10-12] or mock-incubated (non-crosslinked samples, lanes 1-3 and 7-9). Immunoprecipitations were performed using NMS (lanes 1, 4, 7 and 10), anti-T3 antibody UC117-1 (lanes 3, 6, 9 and 12) and anti-TCR $\alpha\beta$ antibody β F1 (lanes 2, 5, 8 and 11) either without (left-hand side) or with (right-hand side) preclearing of TCR $\alpha\beta$ molecules using β F1. Note that a small fraction of radiolabelled TCR $\alpha\beta$ was detected in lanes 2 and 5 (without preclear) but not with the β F1 preclear (lanes 8 and 11). c, IDP2 cell lines 5 (WT31⁺T3⁺) and 7 (88% WT31⁻T3⁺) were ¹²⁵I-labelled, solubilized in 1% Triton X-100 and immunoprecipitated using NMS (lanes 1 and 3) or anti-T3 antibody UCHT-1 (lanes 2 and 4). The T3 heavy subunit (27K) appeared similar in these two cell lines, while the T3 light subunits (19-25K) did not (compare lanes 2 and 4 below the arrowhead). Methods. ¹²⁵I-labelling, solubilization in 1% Triton X-100, immunoprecipitation and visualization after SDS (10.5%)-PAGE by autoradiography were performed as described previously¹²⁸. Chemical crosslinking of intact radiolabelled lymphocytes using DSP (50 μ g ml⁻¹) in PBS (ρ H 8) was for 30 min at 23 °C, as described previously¹²⁸. After immunoprecipitation, all samples were examined by SDS-PAGE under reducing conditions using 5% 2-mercaptoethanol, which cleaved both the disulphide bonds between protein subunits and the DSP chemical crosslink.

tion contained both T4⁻T8⁺ and T4⁻T8⁻ cells (cell lines 3, 6 and 7). Further phenotypic analyses revealed that this population was T11⁺ but negative for natural killer cell markers such as Leu 7, Leu 11 and OKM1 and for the immature thymocyte marker T6 (data not shown).

WT31⁻ T3⁺ cells are negative for TCR $\alpha\beta$

Having identified WT31⁺T3⁺ and WT31⁻T3⁺ populations, we sought to determine whether these lymphocytes expressed TCR $\alpha\beta$ molecules that could be immunoprecipitated by β F1. While β F1 immunochemically defined a heterodimeric structure on the surface of 125 I-labelled WT31+T3+ IDP1 lymphocytes (Fig. 2a, lane 5), it failed to recognize a similar protein on the WT31-T3+ population from the same individual (Fig. 2a, lane 11). Similar analysis of IDP2 cell lines revealed a trace of TCR $\alpha\beta$ on the 88% WT31⁻T3⁺ cell line 7 (Fig. 2b, lane 2) consistent with the 12% contamination with WT31+T3+ cells. Thus, the WT31-T3+ cells, identified by the lack of cell surface reactivity with antibody WT31 on FACS analysis, were also βF1, as determined by lack of TCR $\alpha\beta$ on immunoprecipitation. Note that all WT31+T3+ and WT31-T3+ cell lines expressed similar amounts of T3 as determined by FACS analysis (data not shown) and by immunoprecipitation with anti-T3 antibody (Fig. 2a, lanes 3 and 9, and c, lanes 2 and 4). However, the T3 molecule on WT31⁻βF1⁻T3⁺ lymphocytes was not identical to that on WT31+BF1+T3+ cells, as revealed SDS-polyacrylamide gel electrophoresis (SDS-PAGE). One- (Fig. 2c) and two-dimensional (data not shown) gel analysis indicated that the difference in T3 was restricted to the light T3 subunits, which reproducibly exhibited different SDS-PAGE mobilities (Fig. 2c, arrowhead).

To determine whether the WT31 $^{-}\beta$ F1 $^{-}$ T3 $^{+}$ population lacked TCR $\alpha\beta$ molecules, or alternatively expressed TCR $\alpha\beta$ molecules that failed to react with the monoclonal antibodies used, we analysed the cells for messenger RNAs encoding the TCR α and β proteins. 32 P-labelled complementary DNA clones encoding TCR α , TCR β and T γ were used to probe Northern blots containing whole-cell RNA from WT31 $^{-}\beta$ F1 $^{-}$ T3 $^{+}$ and WT31 $^{+}\beta$ F1 $^{+}$ T3 $^{+}$ IDP2 cell lines and from HPB-MLT, which is known to contain mRNAs for TCR α , TCR β and T γ . No TCR α or β mRNA transcripts were detected in the RNA from the WT31 $^{-}\beta$ F1 $^{-}$ T3 $^{+}$ IDP2 cell line 6 (Fig. 3 α , α -probe, lane 1; or β -probe, lane 1), whereas expression of both was clearly detectable in RNA from HPB-MLT (Fig. 3 α ; α -probe, lane 2; and β -probe, lane 2). Notably, T γ mRNA was present in the

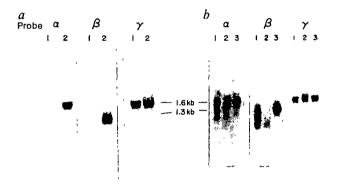

Fig. 3 Northern blot analysis of RNAs isolated from 1DP2 cell lines using TCR α , TCR β and T γ cDNA probes. a, Total RNA (15 µg) isolated from IDP2 cell line 6 (WT31⁻) (lane 1 for each probe) and from T-cell leukaemic line HBP-MLT (lane 2 for each probe) was fractionated on a 1.5% agarose gel containing 2.2 M formaldehyde, transferred to nitrocellulose and hybridized with TCR α , TCR β and T γ probes. b, Total RNAs (2 µg) isolated from IDP2 cell line 5 (WT31⁺T3⁺) (lane 1 for each probe), IDP2 cell line 7 (88% WT31⁻T3⁺) (lane 2 for each probe) and HPB-MLT (lane 3 for each probe) were analysed as in a.

Methods. RNA preparation, electrophoresis, transfer to nitrocellulose and hybridization with 32 P-labelled, nick-translated probes $(1-3\times10^8~\text{c.p.m.}~\mu\text{g}^{-1})$ were done as described previously 41 . The α -chain probes were the human cDNA clones pGA5 (ref. 8) in α and L17 α (ref. 42) in β ; the β -chain probes were human cDNA clones 12A1 (ref. 43) in α and L17 α (ref. 43) in β . The β -chain probe was an β -coal ragment derived from human cDNA clone T γ -1 (ref. 36). Radioactive bands were visualized by autoradiography using intensifying screens. In the experiment shown in β , all probes were labelled to almost identical specific activity, and identical exposure times were used.

WT31⁻T3⁺ cells at a level comparable to that in HPB-MLT (Fig. 3a, γ -probe, lanes 1 and 2). Thus, the WT31 β F1 T3⁺ lymphocytes lacked TCR α and β mRNA. Subsequent experiments on cell lines that were mostly WT31⁻T3⁻ corroborated this result. For example, Northern blot analysis of IDP2 cell line 7 (88% WT31⁻T3⁺) in comparison with IDP2 cell line 5 (WT31⁺T3⁺), as well as with HPB-MLT cells, revealed only a trace of TCR α or β mRNA in the 88% WT31⁻T3⁺ cells (con-

sistent with the 12% contamination with WT31⁺T3⁺ cells) (Fig. 3b, lane 2 for each probe). Further, most of the β transcripts that could be detected were 1.0 and not 1.3 kilobases (kb) long and were probably nonfunctional³⁵. In contrast, the IDP2 cell line 5 (WT31⁺T3⁺) expressed levels of both RNA species which were comparable to those in HPB-MLT (Fig. 3b, lane 1 for each probe). However, like the WT31⁻T3⁺ line shown in Fig. 3a, both the WT31⁻T3⁺ and the WT31⁺T3⁺ lines showed levels of T γ RNA comparable to that in HPB-MLT (Fig. 3b, γ -probe).

Thus, the WT31⁻T3⁺ cells lacked α and β T-cell receptor mRNA (by Northern analysis) and α and β T-cell receptor proteins (by immunoprecipitation and FACS analysis). The presence of T γ mRNA in WT31⁻T3⁺ cells, while consistent with T γ protein expression, could not be taken as strong evidence for this, as many human cell lines that express T γ mRNA of normal size may express full-length transcripts that are out of frame because of defective joining of the V (variable) and J (joining) regions³⁶.

Non- α , non- β T3-associated molecules

We used chemical crosslinking to determine whether proteins analogous to the TCR $\alpha\beta$ molecules existed on the WT31-BF1-T3+ cells. This technique has demonstrated the physical association of the TCR $\alpha\beta$ molecules with the T3 glycoprotein¹². The bifunctional, cleavable reagent dithiobissuccinimidyl propionate (DSP), was used to crosslink 125Ilabelled surface proteins of viable T lymphocytes. After crosslinking, the lymphocytes were solubilized in non-ionic detergent and immunoprecipitated with anti-T3 antibody. As expected, in the WT31⁺ β F1⁺T3⁺ lymphocytes the TCR α - and β -chains were found to be crosslinked to T3. For example, TCR $\alpha\beta$ molecules and T3 were found in anti-T3 or βF1 immunoprecipitates from crosslinked IDP1 cell line 2 (WT31+T3+) (Fig. 2a, lanes 4 and 6). However, despite the lack of reactivity with β F1 and the lack of TCR α or β mRNA, IDP1 cell line 3 (WT31⁻T3⁺) and IDP2 cell line 7 (88% WT31-T3+), both also expressed two protein subunits (55K and 40K) that specifically crosslinked to T3 (Fig. 2a, lane 10 and b, lane 6). Note that the mobilities of these T3-associated molecules were clearly different from those of the TCR α - and β -chains from WT31⁺T3⁺ cell lines (compare Fig. 2a, lanes 4 and 10, or b, lanes 5 and 6).

As IDP2 cell line 7 (88% WT31 $^-$ T3 $^+$) contained 12% WT31 $^+$ T3 $^+$ cells (accounting for the weak β F1 immunoprecipitates noted; Fig. 2b, lane 2), the lysate from these cells was precleared of TCR $\alpha\beta$ protein using β F1. After preclearing, no residual β F1-reactive material could be detected (Fig. 2b, lanes 8 and 11). When this β F1-precleared lysate from crosslinked cells was immunoprecipitated with anti-T3, 55K and 40K subunits were still detected (Fig. 3b, lane 12).

Because these WT31 $^-\beta$ F1 $^-$ T3 $^+$ cell lines do not apparently express TCR α and β mRNAs, the molecules found specifically crosslinked to T3 on their cell surfaces cannot represent proteins encoded by the known TCR α or β genes. We therefore considered the possibility that one of these polypeptides represents the product of the rearranging T γ gene.

Isolation of T3-associated 55K subunit

cDNA clones representing the rearranging human $T\gamma$ gene would encode a polypeptide with a predicted M_r of 40,000 (ref. 36). However, unlike the murine $T\gamma$ gene, which does not reveal any N-linked glycosylation sites¹⁵, the human $T\gamma$ gene has five potential sites for N-linked glycosylation, four of which are located in the constant region³⁶. As a $T\gamma$ protein has not been isolated previously, it is unknown how many of these potential sites are used. However, a fully glycosylated human $T\gamma$ protein may have a M_r of ~55,000. The heavy chain of the non- α , non- β T3-associated subunits identified on the WT31 $^-\beta$ F1 $^-$ T3 $^+$ IDP1 and IDP2 cell lines described in the present report had a relative mobility of 55K on SDS-PAGE (Fig. 2a, b). To determine whether this T3-associated heavy chain was serologically cross-

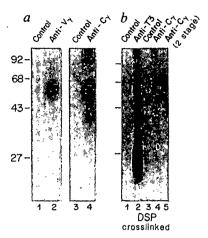

Fig. 4 Immunoprecipitations from IDP2 cell line 7 by anti-V. and anti-C₇ antisera. a, Triton X-100-solubilized, ¹²⁵I-labelled IDP2 cell line 7 (88% WT3 T3 +) was denatured (see below) and then immunoprecipitated with NMS (lane 1) or normal rabbit serum (lane 3) and with anti-V, antiserum (lane 2) or anti-C, antiserum (lane 4). Note that a specific band was observed at M_r 55,000 in both the anti-V, and anti-C, immunoprecipitations. The additional band at Mr 90,000 was not reproducibly observed in the anti-C₂ immunoprecipitations (see b). b, DSP-crosslinked native lysates (1% Triton-100) from ¹²⁵I-labelled IDP2 cell line 7 were immunoprecipitated with NMS (lane 1) or with anti-T3 antibody UCHT-1 (lane 2). Alternatively, the lysate was denatured (as described below) and immunoprecipitated with either normal rabbit serum (lane 3) or anti-C, antiserum (lane 4). An additional aliquot of lysate was subjected to a two-stage immunoprecipitation: polypeptides were immunoprecipitated with UCHT-1, and were eluted from the immunoadsorbent under denaturing and reducing conditions, in order to break the DSP crosslink. Immunoprecipitation from this eluate was then performed using anti-C, antiserum (lane 5)

Methods. 125 I-labelling, solubilization and immunoprecipitation were performed as described for Fig. 1. Native lysates (1% Triton-100) were denatured by adding SDS (final concentration 1%) and dithiothreitol (final concentration 2 mM) followed by heating the mixture for 5 min at 68 °C. After cooling, iodoacetamide was added (20 mM final concentration) and samples were diluted by adding 4 vol. of 1.5% Triton X-100 in Tris-buffered saline (pH 8). The initial immunoprecipitate in the experiment depicted in lane 5 of b was denatured and subsequently partially renatured in a similar manner²⁸. Samples were immunoprecipitated with 10 μl of anti-C. or anti-V, antiserum, 1 µg of UCHT-1 or 1 µl of NMS or normal rabbit serm and analysed by SDS (10.5%)-PAGE under reducing conditions (5% 2-mercaptoethanol). Peptides corresponding to deduced V, or C, amino-acid sequences (residue numbers noted in the text) were synthesized on a Beckman 990 or an Applied Biosystems 430A peptide synthesizer using the method of Merrifield44. Peptide purity was assessed by HPLC and peptide sequences were confirmed by amino-acid analysis. Peptides were coupled to keyhole limpet haemocyanin (KLH) at a ratio of 50 peptides per KLH molecule⁴⁵. Mice and rabbits were immunized with the V_{γ} or C_{γ} peptides, respectively. Animals were injected at 3-week intervals and the antisera screened for binding reactivity on peptide-KLH and peptide-bovine serum albumin conjugates to ascertain the presence of peptide-specific antibodies.

reactive with or identical to the $T\gamma$ protein, antisera were raised against synthetic peptides representing, respectively, a stretch of 17 amino acids (residues 5-21) from the variable region (anti- V_{γ} antiserum) and a stretch of 20 amino acids (residues 117-136) from the constant region (anti- C_{γ} antiserum) of the $T\gamma$ amino-acid sequence deduced from a human cDNA clone³⁶. Both the anti- C_{γ} antiserum and the anti- V_{γ} antiserum immunoprecipitated a molecule with a $M_{\rm r}$ of 55,000 from the denatured lysate of ¹²⁵I-labelled WT31 $^{-}\beta$ F1 $^{-}$ T3 $^{+}$ cells (Fig. 4a, lanes 2 and 4). Such molecules could not be immunoprecipitated from lysates of ¹²⁵I-labelled HPB-MLT cells, which express only nonfunctional $T\gamma$ mRNA³⁶ (data not shown).

To demonstrate that the 55K molecule immunoprecipitated by the anti- C_{γ} and anti- V_{γ} antisera was, in fact, the heavy subunit that crosslinked to T3, an additional experiment was performed (Fig. 4b). A sample of DSP-crosslinked lysate from the WT31⁻βF1⁻T3⁺ cells was first immunoprecipitated with anti-T3, again demonstrating the association of 55K and 40K subunits with T3 (Fig. 4b, lane 2). In parallel, another aliquot of the crosslinked lysate was immunoprecipitated with an anti-T3 monoclonal antibody, and the immunoprecipitated T3-crosslinked polypeptides were eluted from the immunoadsorbent, under denaturing and reducing conditions in order to break the DSP crosslink. This eluate was then re-precipitated with anti-C, antiserum; the 55K subunit that crosslinked to T3 was re-precipitated by the antiserum (Fig. 4b, lane 5), indicating that the 55K subunits defined by these two approaches were identical.

Conclusions

Framework monoclonal antibodies (β F1 and WT31) against the TCR $\alpha\beta$ molecules were used to identify and isolate a WT31⁻\beta F1⁻T3⁺ lymphocyte population from the PBL of two immunodeficiency patients. By the criteria of both immunoprecipitation analysis with framework monoclonal antibody and Northern blot analysis using TCR α - and β -specific cDNA probes, polyclonal human T-cell lines of this phenotype were shown to express neither TCR $\alpha\beta$ mRNA transcripts nor polypeptides. Nevertheless, chemical crosslinking studies using the cleavable DSP reagent revealed the existence of a protein complex associated with the T3 glycoprotein on the surface of these cells. The heavier of the two subunits that crosslinked to T3 (55K) was also immunoprecipitated by two different antisera, one generated against a 17-amino-acid synthetic peptide corresponding to a part of the variable region and another generated against a 20-amino-acid synthetic peptide corresponding to a part of the constant region of the deduced amino-acid sequence of a rearranged $T\gamma$ gene^{19,36}. Thus, it seems that the 55K protein is the T γ protein encoded by the rearranging T γ gene¹⁵ (or, less likely, a protein highly cross-reactive with it). Final proof of this, however, must await protein sequence determination and comparison with the deduced amino-acid sequences of rearranged Ty cDNA clones. The 40K polypeptide appears to be a novel fourth T3-associated protein that we term $T\delta$ (Fig. 2a, b). The T γ and T δ polypeptides may form a T3-associated heterodimeric structure $(T\gamma\delta-T3)$ on these cells that is analogous to the previously described T-cell receptor complex (TCR $\alpha\beta$ -T3). Alternatively, since the cell lines examined are polyclonal, the 55K and 40K polypeptides may occur as monomeric T3-associated subunits on individual T-cell clones.

The complex described here has several important characteristics that might be expected for a second T-cell receptor, that is, it is physically associated with T3 and one of the T3-associated chains is recognized by several anti-Ty antisera. We do not know at present whether the Ty and To components are distinct gene products, whether they are covalently linked via an interchain disulphide bond, whether they display clonal heterogeneity on T cells, or if ligands that react specifically with this protein complex are capable of triggering cell proliferation or factor production as occurs with the TCR $\alpha\beta$. However, in another study, human thymus-derived clones of the same phentoype as the IDP1 and IDP2 cell lines described here (β F1⁻T3⁺) were stimulated to proliferate and to secrete IL-2 in response to anti-T3 antibodies (see page 179 of this issue⁴⁶). Thus, pending the outcome of peptide mapping and additional functional experiments, the T3-associated complex demonstrated here represents a likely candidate for a second T-cell receptor.

The function of the WT31^{- β}F1⁻T3⁺ cells is unknown. Ty mRNA expression is highest early in murine thymic ontogeny and declines thereafter, suggesting that the Ty polypeptide may be functionally important only early in thymic ontogeny^{37,38}. Since the putative second T-cell receptor complex reported here has been identified in immunodeficiency patients, it may be expressed on cells arrested at an early stage of thymic ontogeny in these patients. For example, about 50% of the WT31 $^-\beta$ F1 $^-$ T3 $^+$ cells were T4 $^-$ T8 $^-$ T3 $^+$, which is similar in phenotype to an identified subpopulation of human thymocytes (ref. 39 and J. Allison and L. Lanier, personal communication). However, it is clear that the $\beta F1^{-}T3^{+}$ phenotype occurs on a subpopulation of normal human PBL (Fig. 1c). These PBL may similarly express the non- α , non- β T3-associated complex described here. If so, this putative second T-cell receptor may occur on mature cells of a lineage which is separate, although related, to that of TCR αβ-expressing T cells. Additional characterization of these novel T3-associated molecules and the cells that express them may further our understanding of T-cell ontogeny as well as mature T-cell function.

We thank Drs W. Tax, I. Trowbridge and P. Beverley for providing monoclonal antibodies, Drs S. Burakoff, T. Springer and J. Fraser for critical comments on the manuscript, and B. Hoffman for assistance with two-colour cytofluorographic analysis. This work was supported by grant ACS-NY-IM-425, NIH grant 5-RO1-AI15669, grant 2P050AI21163 and by grants from the Leukemia Research Foundation and from Hoechst Aktiengesellschaft.

Note added in proof: The 55K and 40K T3-associated polypeptides on IDP2 cell lines are not disulphide-linked.

As one of the nearest examples of an active galaxy, NGC5128 (Centaurus A) has been studied in detail over a wide range of wavelengths1. The nucleus of the galaxy is seen clearly in the X-ray, radio and infrared, but is obscured in the optical by the prominent warped dust lane. We have made polarization observations of the infrared nucleus at wavelengths from 1.2 to 3.8 µm. We find that after correction for the polarization caused by the dust lane, and for dilution by starlight, the nucleus has a large intrinsic polarization of $\approx 9\%$ at position angle 147°. This position angle is perpendicular to the direction of the X-ray and radio jet. We interpret the polarized emission from the nucleus as synchrotron radiation from a region whose magnetic field is parallel to the jet direction. The properties of the Cen A nucleus are essentially identical to those of the much more luminous blazars 17. This suggest that blazar-type activity extends over a very wide range in luminosity, and low-luminosity blazars may be common in elliptical galaxies.

Polarimetry and photometry of NGC5128 in the J(1.20 µm), H(1.64 µm) and K (2.19 µm) bands were obtained on 26 June 1985. Polarimetry in the L' band (3.8 µm) was obtained on 2 and 3 July 1985. All observations were made using the 3.9-m Anglo-Australian telescope and the Hatfield polarimeter². The position angles were calibrated using an internal calibration polarizer and standard stars for J, H and K, and an observation of the W33A infrared source³ for L'. The J, H and K observations were each obtained through apertures of nominal size 8, 4.5 and 2.25 arc s, centred on the peak 2.2-µm signal. Some vignetting was introduced by the wire grid polarizer, so the response was not flat over the full aperture. The seeing disk size was ~1 arc s (full width at half maximum) and the photometry was calibrated using standards observed through the same set of three apertures. The photometry and polarimetry results are given in Table 1.

Optical polarimetry of several points in the dust lane has been published by Elvius and Hall⁴. These observations show typical polarization position angles of $\sim 115^{\circ}$ near the nucleus. This polarization can be understood as being caused by absorption

Table 1 Polarimetry and photometry of NGC5128

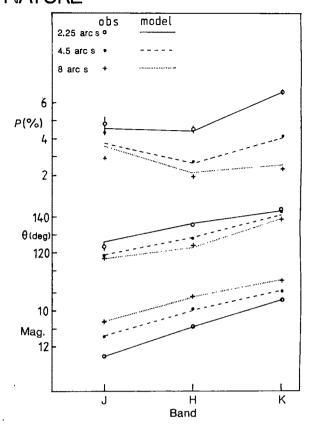

Fig. 1 Observations (points) of the polarization, position angle and magnitude of NGC5128 (Cen A) compared with the predictions (lines) of a model composed of a power-law polarized nucleus stellar component and dust lane polarization, as described in the text. Aperture sizes: $2.25 (\bigcirc, ---)$; $4.5 (\bigcirc, ---)$ and $8 (+, \cdots)$

by dust grains aligned by a magnetic field in the plane of the dust lane; thus, it can be expected to display the same wavelength dependence observed for interstellar polarization in our own Galaxy⁵, and decrease into the infrared. The polarizations we observe in the J band in the largest aperture show approximately the same position angle as this dust lane component, but as we go to smaller apertures and longer wavelengths we find increasing polarizations, and a tendency for the position angle to swing to larger values. This effect can be readily understood if the very red point-source nucleus⁶ has its own intrinsic polarization with a position angle different from that caused by the dust lane. Smaller apertures and longer wavelengths give increasing contributions of the nucleus relative to the stellar component of the galaxy, and thus a total polarization and position angle closer to that of the nucleus.

Using the multi-aperture observations we can derive the flux and polarization of the annuli between 2.25 and 8 arcs, and between 4.5 and 8 arcs. Although there are differences between the two annuli, the K-band polarizations are very small (~0.5%, compared with the 6.63% measured in the smallest aperture), confirming that the polarization is predominantly due to the nucleus itself. The light contained within the smallest aperture will be that from the polarized nucleus itself, and the contribution from starlight. We can reasonably assume that the starlight within the smallest aperture has the same colours and polarization as those observed for the annuli. We can set reasonable limits on the relative contributions to the flux, by requiring that the nuclear flux at J must be greater than zero, but must not be so large that the surface brightness of the stellar component would decrease inwards.

Using the above procedure, we find a range of values of the polarization of the nucleus. The K polarization must be in the range 8.8-11.1%, the H polarization in the range 7.2-15.4%, and the J polarization must be >7.1%. The smallest values correspond to the largest flux contributions from the nucleus. Thus, this analysis suggests a polarization which is either relatively flat with wavelength or increases to the blue.

We have obtained a good fit to the data with a model consisting of the following components (see Fig. 1 and Table 2): (1) A power-law nucleus with a wavelength-independent polarization of 9% at position angle 147°, spectral index 5.3, and J-band flux of 3.0 mJy. (2) A stellar component with spatial flux distribution adjusted to fit the J photometry, and colours equal to those observed for the 4.5-8 arcs annulus. (3) A polarization due to the dust lane, applied to both of the above components, following a Serkowski law with $P_{\text{max}} = 7\%$, $\lambda_{\text{max}} = 0.55 \,\mu\text{m}$ and position angle = 115° .

The fit is generally good. The discrepancies in the J-band polarization are probably due to the patchy nature of the dust lane⁷, causing its polarization to change over the spatial scale of the observations. Slight discrepancies in the fit to the flux indicate that a power law is not an accurate representation of the spectrum. A reddened power law may fit the data better, but the degree of reddening appropriate for the nucleus is uncertain. The L' polarization is a little lower than predicted by the model, perhaps indicating some additional source of dilution (such as thermal radiation from the dust lane as seen at 10 µm

There is evidence that the nucleus of Cen A has a much higher extinction than the A_v of 5-6 mag (ref. 9) due to the dust lane. The silicate optical depth implies $A_V = 22 \text{ mag}$ (ref. 10), and the hydrogen column density derived from X-ray absorption implies $A_v = 45 \text{ mag}$ (ref. 11). However, the wavelength dependence which we observe for the polarization of the nucleus does not rise to the blue steeply enough for the polarization to be due to dichroic absorption in this thick dust shell. A small contribution to the polarization arising from the dust shell, in addition to a flatter intrinsic polarization from the nucleus, cannot be

The position angle of the X-ray jet is $53 \pm 1^{\circ}$ (ref. 11), and that of the radio jet is $55 \pm 7^{\circ}$ (ref. 12). The polarization position angle we observe for the nucleus is almost exactly perpendicular to these jet position angles and suggests that the polarized infrared radiation is associated with the inner jet. Antonucci¹³ has noted other cases of radio galaxies with polarization perpendicular to the radio structure.

Models proposed for the nucleus of Cen A14-16 explain its infrared flux as synchrotron radiation, with inverse Compton scattering of the infrared photons giving rise to X-ray emission. Our observation of high polarization for the infrared nucleus provides strong support for such synchrotron models. The observed position angle then indicates that the magnetic field must be aligned predominantly along the jet direction. The only other plausible origin for the infrared nucleus is thermal reradiation by dust grains, which could produce a high polarization if the emitting grains has a high degree of alignment. However, Grasdalen and Joyce¹⁰ have considered this thermal

re-radiation model and find that it cannot account for the observed infrared flux.

The class of blazars¹⁷ includes the BL Lac objects and the highly polarized quasars. Such objects are considered to be normally found in the nuclei of giant elliptical galaxies, possess compact radio sources with flat or inverted spectra and highly polarized, smooth optical/infrared continua, and are subject to violent variability. The observation of a highly polarized infrared continuum shows that all of these properties are shared by the nucleus of Cen A, with the possible exception of violent variability. There is no evidence for variability of the infrared nucleus of Cen A, although this may be due to insufficient observations. The existence of variability of the Cen A nucleus at X-ray wavelengths is well established11. Studies of BL Lac objects show that the most violently variable objects are those of highest luminosity, with low-luminosity objects tending to show less variability and polarization with preferred position angles¹⁷. Similar effects can be seen in individual objects, such as BL Lac, which shows well-defined position angles when it is faint18 Thus, the absence of violent variability in Cen A, which is substantially less luminous than a typical blazar, need not preclude it being closely related to such objects. BL Lac objects typically show polarization which is either flat with wavelength of decreases to the red^{19,20}, consistent with what we see in Cen A.

The luminosity of the Cen A nucleus in the 1-2-\mu m region is

uncertain due to the unknown extinction, but is probably <10⁴² erg s⁻¹. The luminosities of BL Lac objects²¹ in the same spectral region range from 10⁴⁴ to 10⁴⁷ erg s⁻¹. However, the existence of blazar activity at such low luminosities is not surprising. Individual blazars (for example, 3C279²²) can vary by as much as a factor of 500. This range presumably reflects changes in the accretion rate onto a massive black hole. It is also thought that relativistic beaming may result in enhancements in apparent luminosity of up to a factor of 100 in the most luminous objects²³. Thus, a blazar which is currently at a low accretion rate, and is not beamed towards us, could have a luminosity lower by a factor of ≥50,000 than that of the most luminous examples. Cen A may well be such an object. Other probable examples of low-luminosity blazar activity are IC5063, which has an infrared nucleus 24 which we have recently found to be highly polarized, and NGC1052²⁵. Such objects may be relatively common, but in galaxies at distances much greater than that of Cen A they would become very difficult to find, because the stellar flux from the galaxy would dominate over the polarized non-thermal emission from the nucleus.

Nearly all of the known y-ray bursts (GRBs), when observed over the energy range ~30 keV to 1 MeV, have intensity spectra that can be described in terms of several-hundred-keV exponential functions. The Venera 11 and Venera 12 KONUS data indicate that, in addition to these 'normal' GRBs, there might exist a separate class of short, soft events^{1,2}. There can be little doubt that bursts with spectra that seem anomalously soft (e-folding energy ≤30 keV) do exist, and that the most convincing known examples—GB790305b (the famous 5 March burst, including its follow-on events), GB790324 (and its follows-ons) and GB790930—generally have atypically short durations of ~0.1-0.25 s. (Three of the 11 GB790305b follow-on events were longer³.) However, because most GRB instruments were designed primarily for observations above ~100 keV, events with very soft spectra have not been well enough studied to be classified unambiguously. Here we present the results of fortuitous detections of GB790107 (determined in ref. 2 to have a soft spectrum) with instrumentation better suited for the study of such bursts. Above 20 keV the spectrum is indeed much softer than any other cosmic event observed through the apertures of these experiments, and does not appear to belong to the general GRB spectral distribution. However, in the 5-15-keV range the spectrum is very flat. Statistical arguments indicate that soft-spectrum events might belong to a disk population, but this is not a strong conclusion.

By virtue of their ~20-keV thresholds, the KONUS experiments have been, until now, the only sources of data on bursts (apart from the 5 March event) with spectra that might be anomalously soft. These observations, although valuable, have significant limitations imposed by the KONUS 20-keV thresholds and 4-s accumulation times for spectral measurements. Clearly, information at lower energies and with better time resolution is required for the study of events having typical energies of ≤30 keV and durations of ~0.2 s. However, experiments with appreciably lower energy thresholds must be collimated to avoid excessive background rates caused by the diffuse X-ray background. Thus, we were fortunate to have simultaneously observed GB790107 down to 5 keV with 0.5-s spectral time resolution with a collimated instrument on the International Cometary Explorer (ICE) spacecraft⁴, and down to 13 keV with 0.25-s resolution with a collimated instrument on Prognoz 7 (P7)⁵. Unfortunately, however, GB790107 was not observable by most GRB instrumentation, due to low instrumental sensitivities below 30 keV. Thus, the detection in the near future of additional similar events could perhaps best be accomplished by examining the 5-100-keV ICE real-time data record, which spans ~6 yr at high duty cycle, with good spatial coverage and 0.5-s time resolution. (As mentioned below, we have already searched the equivalent of a 70-day, 100%-duty-cycle block of these data.)

Because of the brevity of GB790107 and the fact that its spectrum was too soft to trigger the high time-resolution memories of most GRB experiments, a well-resolved time history (energy-integrated) was obtained only by the KONUS experiment (Fig. 1 inset). The outburst had a duration of ~ 0.2 s and

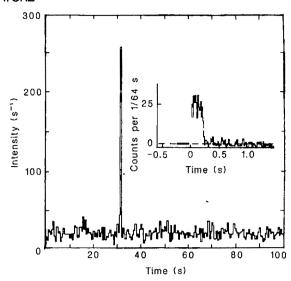

Fig. 1 Time histories of GB790107. The inset is the KONUS energy-integrated time history, and the main plot is the ICE 25-40-keV response. This was one of the most intense cosmic events ever seen in ICE data in this band, but its flux above ~100 keV was unobservable at current instrumental sensitivities.

a rather flat-topped profile. The ICE response in the 25-40-keV band (Fig. 1) is one of the most intense ever recorded by that instrument from a cosmic source. The P7 and ICE data records do not resolve the main spike, but the continuous ICE time coverage with 0.5-s resolution allows one to search for slow structure, such as '5 March-like' pulsations. As can be seen from Fig. 1, there are no indications of any such structure, although appropriately scaled-down GB790305b pulsations would not be observable.

Figure 2 shows the GB790107 spectral data. Because of the uncertainty in the source location, the absolute normalizations of the spectra measured by the collimated instruments on P7 and ICE are uncertain by about ±25%. The normalizations used in the figure assume the highest source exposures that are consistent with the time-of-arrival error box. Also, a spacecraft strut that is sometimes in the ICE field of view could give rise to an additional 25% systematic error below 15 keV for this event. Our conclusions are not affected by either the normalization or the 'strut-absorption' uncertainties. Above ~30 keV the spectrum is extremely steep for a GRB, corresponding to a temperature of ~10 keV if fit by a Planck function or ~30 keV if fit by optically thin thermal bremsstrahlung. (The GB790305b and GB790324 follow-on events had similar temperatures².) However, our data show that the steepness does not extend to lower energies; the 5-7-keV upper limit is comparable to the measured intensity at 30 keV. The high-energy 'tail' which seems to be present in the KONUS spectrum was not detected by the other experiments, even though their sensitivities were adequate. Even without the tail, simple models can reproduce the data only if some means of explaining the lack of low-energy photons is provided. It may be noteworthy that the thermal cyclotron model, with its lack of emission below the first harmonic, can provide a 'natural' low-energy cutoff if the magnetic field in the emission region is $\sim 10^{12}$ G.

The time history and spectral information give some insight concerning whether GB790107 belongs to, or is closely related to, any other known class of high-energy transient. First, we note that the only other cosmic events having a comparable 25-40-keV intensity in ICE records (GB781104b, GB790305b, GB820801 and GB840304) were among the most powerful GRBs ever observed at energies >100 keV. At these 'typical' GRB energies, GB790107 is at least ~2 orders of magnitude weaker than the aforementioned strongest bursts. None of the ~100 other known ICE events had an intensity in the 25-40-keV band

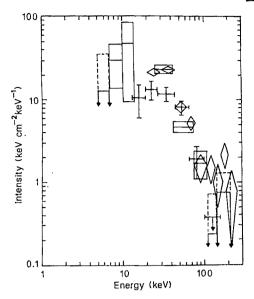

Fig. 2 GB790107 spectra. The plot is non-standard for γ-ray bursts in that it is an intensity spectrum rather than a number spectrum. This representation generates a clearer picture of the very steep GB790107 spectrum. Rectangles, ICE; crosses, P7; diamonds, KONUS data. The upper limits are shown at 10 (solid lines) and, for ICE, 2\sigma (dashed lines) confidence levels. The integration times for the spectra are 0.5 s for ICE and P7, and 4 s for KONUS. The burst duration was 0.2 s.

greater than one-quarter that of GB790107. It is therefore difficult, but not impossible, to believe that GB790107 is a member of the 'classical' GRB population. Furthermore, its short duration and high (>10 keV) temperature set it well apart from X-ray bursters, and its brevity and lack of a prominent gradual X-ray component differentiate it from solar flares. The only events both spectrally and temporally similar to GB790107 are the follow-on events associated with GB790305b and GB790324. (GB790107 does resemble spectrally the impulsive components of some solar flares, and a weak, gradual component could have gone undetected. This might be a clue to the emission mechanism.)

The GB790107 localization information is derived from wavefront arrival times at Venera 11, P7 and ICE, and from the responses of the collimated ICE and P7 instruments. The error box (more properly, the 'error arc') is defined by the intersection of the following areas: (1) the P7/KONUS arrival-time annulus of radius 33.475 \pm 0.012° centred at $(\alpha, \delta)_{1950} = 15 \text{ h} 43 \text{ min } 53.6 \text{ s}$, -18° 04′ 53"); (2) an 8° full-width band, centred on the ecliptic plane, inferred from the relative ICE response; and (3) a region ~15° by 20°, centred near $(\alpha, \delta) = (18 \text{ h } 20 \text{ min, } -25°)$, determined from the P7 response. The intersection of these regions is a curved strip, 8° by 0.024°, whose midpoint is at $(\alpha, \delta)_{1950}$ = (18 h 05 min 36.8 s, $-23^{\circ}26'22''$) or $(l_2, b_2) = (7.36, -1.71)$. A search through catalogues of flare stars, pulsars and high-energy emitters (~25,000 objects) revealed two in the box. These were the pulsar PSR1804-27 (ref. 6) and V2 57, an early-type star with emission lines⁷. In this region of the sky there are several catalogued objects per square degree, so chance coincidences are not unlikely. Also, due to its own location uncertainty, the pulsar may not be in the GRB error box.

Perhaps the most significant question about the error box concerns what its proximity to the galactic centre (GC) tells us about the spatial distribution of this type of event. The following additional facts are relevant: (1) The localized events that are spectrally and temporally most similar to GB790107 (that is, GB790305b and GB790324) are located at $(l_2, b_2) = (275, -33)$ and (47, 4). (2) GB790930, the most certain (in our judgment) other identification of a short event with a soft spectrum, did not produce a response in ICE, and was therefore at least 30°

from the GC (but not necessarily out of the plane). (3) If the flat top of the GB790107 time history is caused by the Eddington limit, then the distance to the source is ~1 kpc, and the low longitude is due to chance. (4) The ICE experiment, whose field of view always includes most of the GC region, has not observed a single additional cosmic event with a comparably soft spectrum. (Our searches have included lists of suspected events^{1,2,8,9} based on their short durations or published spectra, as well as an arbitrary 70-day-equivalent data block. The other ~10 short events observed by ICE had hard spectra.) These facts all imply that there is not much concentration in galactic longitude, although the three known locations are at low latitudes. A disk distribution may thus be indicated but this is not a strong conclusion.

There remain many basic questions concerning the spatial, temporal (both frequency of occurrence and time history) and spectral distributions of soft bursts. Until we obtain some of the answers (or the basic GRB mechanism becomes well understood) we cannot state definitively that GB790107 and other soft events constitute a true 'class', as opposed to being merely 'extreme' examples of GRBs.

The Los Alamos authors thank R. Robinson, whose efficient and well-organized data reduction methods have enabled us to use the ICE and Pioneer Venus Orbiter databases to an extent not previously possible. We also thank R. Epstein for carefully reading the manuscript and providing helpful comments. This work was supported by the US Department of Energy and NASA under contract NAS5-22307, and by CNES contract 82-212. Note added in proof: We have recently discovered multiple (perhaps >50) recurrences of GB790107 in 1983. This confirms its similarity to the March 1979 repeating sources, and strengthens the interpretation that these objects are members of a distinct 'class'.

Department of Physics and Astronomy, Northwestern University, Evanston, Illinois 60201, USA

The discovery of a second millisecond binary radio pulsar¹, PSR1855+09 (period P=5 ms), with a relatively wide circular orbit and low mass function indicates that the incidence of such systems (see also refs 2, 3) among the galactic radio pulsar population is $\sim 4 \times 10^{-3}$. The generally accepted model for the origin of these systems is that they have descended from low-mass X-ray binaries in which a weakly magnetized neutron star³ was spun-up by the accretion of matter from an evolved low-mass (≤1.2 M_{\odot}) companion star, which has now ended its life as a helium white dwarf³⁻⁸. We show here that, based on the incidence of the progenitor low-mass X-ray binaries (LMXBs), the observed incidence of millisecond binary radio pulsars can be explained only if, at their present low field strength of $\sim 10^9$ G, the decay timescale of neutron-star surface magnetic dipole moments is $\geq 10^9$ yr. This possibility has been advanced by Kulkarni⁹, who estimates, based on the optical detection of the counterpart of the weak-field binary radio pulsar PSR0655+64, that this pulsar is old ($>5 \times 10^8$ yr) and hence that the magnetic field decay timescale becomes very large ($>10^9$ yr) for field strengths $\leq 10^{10}$ G. Our findings provide independent support for this possibility.

The progenitor LMXBs, in which the companion stars are evolved, are strong sources, of X-ray luminosity $L_{\rm X} \simeq (0.2-1)\times 10^{38}\,{\rm erg\,s^{-1}}$, such as the strong galactic bulge sources, Sco X-1 and Cyg X-2 (ref. 10). There are at most 30-50 such sources in the Galaxy¹¹, of which about a dozen are located in the galactic bulge. The typical X-ray lifetime of these systems, based on their accretion rates (\dot{M}) of $\sim (0.2-1)\times 10^{-8}\,M_{\odot}\,{\rm yr}^{-1}$ and companion mass $\sim 1\,M_{\odot}$, is $\sim 2\times 10^8\,{\rm yr}\,{\rm (ref.\,12)}$. This implies a formation rate of these luminous LMXBs of at most $(1.5-2.5)\times 10^{-7}\,{\rm yr}^{-1}$. Assuming all such systems to leave millisecond binary radio pulsars, the number of millisecond binary radio pulsars formed during the $\sim 1.5\times 10^{10}\,{\rm yr}$ lifetime of the Galaxy is $\sim 3\times 10^3$ (in a steady state, their formation rate will be the same as that of the luminous LMXBs).

As pointed out by Taam and van den Heuvel¹³, the presently available data on magnetic field strengths of neutron stars in binaries are consistent with the hypothesis that neutron stars are born with surface dipole field strengths $B_s = 10^{12} - 10^{13}$ G, which decay exponentially on a timescale of $\sim 5 \times 10^6$ yr for $\sim 7-10$ e-foldings, that is, down to at least 10^9-10^{10} G. In order to become a millisecond pulsar, that is, to reach $P_{\text{rot}} \leq 5 \text{ ms by}$ spin-up, B_s should have decayed to $<3 \times 10^9$ G before the end of the accretion spin-up phase, as otherwise, even at $\dot{M} = \dot{M}_{\rm Edd}$ (the accretion rate corresponding to the Eddington limit), such a short period cannot be reached (see refs 8, 13, references therein, and equation (1), below). If the surface dipole fields of such pulsars were to keep decaying beyond this value on a timescale of $\sim 5 \times 10^6$ yr, the field strengths of these millisecond pulsars would drop below 5×10^7 G within $\sim 2 \times 10^7$ yr after the end of the accretion spin-up phase, rendering them virtually unobservable as pulsars (no known radio pulsar has a field strength of $<4.5\times10^8$ G). With the formation rate in the Galaxy derived above, this maximum lifetime of $\sim 2 \times 10^7$ yr as a millisecond pulsar would imply that, at any time, at most only three to five millisecond binary radio pulsars would be observable in the entire Galaxy. The total number of active radio pulsars in the Galaxy is estimated to be $(1-5) \times 10^5$ (ref. 14), leading to an expected incidence of millisecond binary pulsars among radio pulsars of at most 6×10^{-6} to 6×10^{-5} .

In contrast with the above estimate, among the ~ 500 known radio pulsars, there are already two millisecond binary pulsars (1953+29 and 1855+09). The distances of these two systems as inferred from their dispersion measures (~ 3 and 0.3 kpc, respectively) are in the same range as those of most of the known radio pulsars. The incidence of binary millisecond pulsars in the general pulsar population is therefore likely to be of the same order as their incidence among the known sample of pulsars, which is $\sim 4 \times 10^{-3}$. This is $\sim 10^2 - 10^3$ times higher than expected under the assumption that at $B_s < 3 \times 10^9$ G the fields continue to decay on a timescale of $\sim 5 \times 10^6$ yr.

Apparently, the latter assumption cannot be correct. The only solution to this problem seems to be that, once the surface dipole field strength has decreased to $\leq 3 \times 10^9$ G, the decay timescale of the field has increased by a factor of 10^2-10^3 over that at $B_s = 10^{12}-10^{13}$ G. Therefore, at $B_s < 3 \times 10^9$ G the field decay timescale must thus be at least $\geq 10^9$ yr, and possibly $\geq 10^{10}$ yr. As the fields of the binary radio pulsars PSR1913+16 and PSR0655+64 are already close to this boundary $(2.2 \times 10^{10}$ and 1.3×10^{10} G, respectively; see ref. 13), they may be expected to

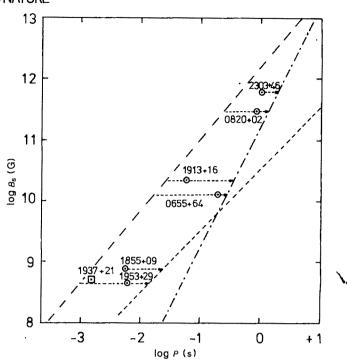

Fig. 1 B_s versus P diagram, showing the positions of the six binary pulsars with known \dot{P} values, together with the 'spin-up line', P_{\min} ($\dot{M}_{\rm Edd}$, B_s), given by equation(1) (———), the deathline³ (—·—·) and the P_f line (the final period reached after a Hubble time, if spin-down proceeds at constant B_s (---). The figure shows that spun-up pulsars with $B_s < 6.10^9$ G need longer than a Hubble time to reach the deathline (assuming evolution at constant B_s).

decay much more slowly than the fields of young, strong-field pulsars. These pulsars may therefore be considerably older than their formal ages, calculated with a field-decay timescale of $\sim 5 \times 10^6$ yr, would indicate. This gives independent support for the high age ($\ge 10^9$ yr) of PSR0655+64 as inferred from the faintness of the optical counterpart of its companion.

With an incidence of at least $\sim 4 \times 10^{-3}$ among the $(1-5) \times 10^{5}$ radio pulsars in the Galaxy, the total number of active binary millisecond pulsars is expected to be between at least ~ 400 and 2,000. Among these, the fraction in globular clusters is expected to be an order of magnitude less than one would infer on the basis of the incidence of LMXBs in such clusters. This is because in a globular cluster a neutron star in a binary may many times capture a fresh companion by means of an exchange collision¹⁵⁻¹⁷, thus lengthening its X-ray lifetime by an order of magnitude. Based on the number of strong sources in globular clusters (~ 10), this yields a formation rate of millisecond pulsars of $5 \times 10^{-9} \, \mathrm{yr}^{-1}$ in the globular cluster population, which, with a lifetime of $10^9 - 10^{10} \, \mathrm{yr}$ yields $\sim 5 - 50 \, \mathrm{active}$ binary millisecond pulsars. A pulsar survey of globular clusters would therefore be valuable.

Upper limits to the ages of the six binary radio pulsars with known period derivative (\dot{P}) can be obtained by assuming that they have all been spun up during the accretion phase to the shortest possible spin period P_{\min} (\dot{M}, B_s) , and have subsequently spun down as radio pulsars to their present pulse periods, at a constant value of B_s . P_{\min} is given by 8,13,18

$$P_{\min} = (1.9 \text{ ms}) B_9^{6/7} (M/1.4 M_{\odot})^{-5/7} (\dot{M}/\dot{M}_{\rm Edd})^{-3/7} R_6^{18/7}$$
 (1

where B_9 is the neutron-star magnetic field in units of 10^9 G, M is the mass of the neutron star, \dot{M} the accretion rate and R_6 the neutron-star radius (in units of 10^6 cm). With $\dot{M}=\dot{M}_{\rm Edd}$, $M=1.4~M_{\odot}$ and $R_6=1$, the values of $P_{\rm min}$ in Table 1 are obtained. The spin-down time from this period to the presently observed

Calculations assume $M = 1.4 M_{\odot}$, $I_{45} = R_6 = 1$.

spin period, at constant B_s, is then obtained by integrating the spin-down equation²:

$$(P\dot{P}) = R_6^6 I_{45}^{-1} B_s^2 / (1.024 \times 10^{39}) \text{ s}$$
 (2)

where I_{45} is the moment of inertia of the neutron star in units of 10⁴⁵ g cm². The resulting ages, listed in Table 1, are upper limits to the ages of these pulsars, because if B_s at the end of the spin-up phase was larger than at present, their true ages will be smaller.

Table 1 shows that PSR2303+46, PSR0820+02 and PSR1913+16 cannot be older than $\sim 0.33 \times 10^8$, 1.2×10^8 and 1.0×10^8 yr, respectively. On the other hand, PSR1855+09. PSR0655+64 and PSR1953+29 might be as old as 0.7×10^9 , 4×10^9 and 3×10^9 yr.

Table 1 also lists the final spin period, P_t , attained by each pulsar, one Hubble time (~1.5×10¹⁰ yr) after its birth at P = P_{\min} , if the surface dipole field remains constant. These periods are derived from the integration of equation (2), which yields

$$P(t)^2 = P_0^2 + 1.95 \times 10^{-21} R_6^6 I_{45}^{-1} B_9^2 t$$
 (3)

Also shown in Table 1, as well as in Fig. 1, are the turn-off periods, Pt.o of these pulsars, corresponding to the 'deathline' (see ref. 3), for evolution at constant B_s , and the lifetimes, $\Delta t_{t.o.}$, until reaching the deathline.

Table 1 and Fig. 1 show that the four binary pulsars with the largest B_s values will reach the deathline within one Hubble time. If their fields were to decay, their final periods would be shorter and they might remain observable for a Hubble time. (Note, however, that PSR1913+16 will coalesce with its companion due to gravitational radiation losses within $\sim 3 \times 10^8$ yr, long before it reaches the deathline 19.) On the other hand, PSR1855+09 and PSR1953+29 do not reach the deathline within a Hubble time. (The same holds for the 1.55-s single pulsar PSR1937 + 21, which has $B_c = 5 \times 10^8$ G, and is also expected to have had a history of spin-up in a binary system, although of an entirely different type (see refs 13, 20, 21, and references therein).) These three pulsars may therefore 'live forever'. These conclusions are in agreement with and provide added support for the findings of Kulkarni⁹.

As to the interpretation of the 'asymptotic' field strength: according to the work of Ruderman and co-workers²² the crustal currents that support the huge exterior magnetic field (~10¹²-10¹³ G) of a newborn neutron star decay on a timescale of ~10⁷ yr by ohmic dissipation. In contrast, any residual magnetic field arising from core currents will have a much longer lifepossibly longer than a Hubble time-due to proton superconductivity in the core (see also refs 23, 24). In this interpretation, the resulting asymptotic field strength is not expected to be the same for all neutron stars, as the strength of the core currents, frozen in at the time of collapse, will depend on the individual history of the parent star (for example, its rotation and magnetic field).

An alternative, purely phenomenological interpretation, consistent with the observations listed in Table 1, is that magnetic fields of non-accreting neutron stars do not decay at all (a

possibility suggested by Kundt²⁵), but that accretion gradually weakens the field. Indeed, in the long-lived (≥108 yr) LMXBs which produced the binary millisecond pulsars PSR1953+29 and PSR1855+09, the neutron stars are expected to have accreted >0.1 M_{\odot} , and possibly as much as 1.0 M_{\odot} (refs 7, 13). The same holds for the millisecond pulsar PSR1937+21 (refs 8, 18). On the other hand, PSR2303+46, PSR1913+16 and PSR0655+46, which have much stronger fields than the three millisecond pulsars, are expected to have accreted $\leq 0.01 M_{\odot}$, as they have descended from massive X-ray binaries in which the accretion phase lasted $<10^6$ yr (refs 7, 8, 13). The same holds for PSR0820+02, where, again, the accretion phase lasted less than a few million years^{7,8,13}.

We cannot offer an explanation for a possible relationship between field decay and amount of matter accreted. It seems conceivable, however, that both the crustal and interior structure of a newborn neutron star that formed in the liquid state at $T > 10^{10} \,\mathrm{K}$ and subsequently cooled and underwent crustal freezing²², is quite different from that of a neutron star that subsequently underwent considerable accretion at relatively low temperatures ($T < 10^8$ K).

It is not now possible to decide which of the two alternative interpretations of the asymptotic field behaviour is the correct one, although the first-mentioned one appears most plausible to us.

After submission of this paper we received a preprint by Bhattacharya and Srinivasan²⁷, who independently, and from a somewhat different viewpoint, also reached the conclusion that the decay timescale of the magnetic fields of binary millisecond pulsars must be $\sim 10^9$ yr.

We thank S. Kulkarni for a preprint and stimulating correspondence, which provided an important trigger for the work reported here.

Inhibition of convective collapse of solar magnetic flux tubes by radiative diffusion

P. Venkatakrishnan

Indian Institute of Astrophysics, Bangalore 560034, India

Interaction of convection with a magnetic field leads to an intermittent distribution of magnetic flux¹. Such a process operating on the solar surface can lead to 'equipartition' fields of 700 G (ref. 2). These fields are further prone to a convective instability and eventually collapse to kilogauss intensity3-5. I show here that radiative diffusion can inhibit this collapse to a varying degree, depending on the field strength and the thickness of the flux elements. As a consequence, one would expect the field strength of the photospheric magnetic flux elements to depend on their sizes. It is shown that at one end of such a distribution there would be kilogauss tubes with small dispersion in field strength and large dispersion in size. At the other extreme of the spectrum would be thin tubes of fairly constant size but with a wide range in field strength, from kilogauss intensities to the equipartition values of 700 G. High-resolution observations from space-borne telescopes should reveal the existence of the latter variety of tubes.

An approximate but effective method of examining the stability of magnetic equilibria resembling solar flux tubes is to use the slender-flux-tube equations ⁶. The linearized equations for slender, radiating, optically thin flux tubes have been considered by Webb and Roberts ⁷ in the context of radiative damping of tube waves. One can use the same equations for optically thick tubes by re-defining the radiative relaxation time τ_R of ref. 7 as $\tau_R = 4\chi/r_0^2$ where χ is the radiative diffusivity and r_0 is the cross-sectional radius of the tube ⁸. For mathematical simplicity and to focus attention on the physics of the problem, we assume isothermal stratification in the tube. The imposition of boundary conditions of vanishing velocity perturbation at the two ends of the tube on equation (12) of ref. 7 (after correcting a misprint in that equation by replacing Λ^2 with Λ_0) leads to the following dispersion relation:

$$\tilde{\sigma}^3 + a_2 \tilde{\sigma}^2 + a_1 \tilde{\sigma} + a_0 = 0 \tag{1}$$

where $a_0 = \varepsilon b_0/\delta$, $a_1 = -\{(1-\gamma)(1+\beta_0)/2 - \gamma b_0\}/\delta$, $a_2 = \varepsilon (1+\beta_0/2)/\delta$, $\delta = (1+\gamma\beta_0/2)$, $b_0 = 1/16 + \pi^2 n^2 \Lambda_0^2/d^2$, $\varepsilon = \tau_D/\tau_R$, $\tilde{\sigma} = \sigma \tau_D$ and $\tau_D = (\Lambda_0/g)^{1/2}$. Here, σ is the complex frequency of the perturbation, assumed to grow in time as $e^{\sigma t}$, β_0 is the ratio of gas pressure to magnetic pressure in the tube, n is the harmonic of the perturbation, d is the length of the tube, Λ_0 is the isothermal scale height of the atmosphere and g is the acceleration due to gravity. To simulate a superadiabatic temperature gradient (necessary for convective collapse) one must assume $\gamma < 1$. Although this is strictly unphysical, it may be used for purely illustrative purposes. Note that choosing a non-isothermal stratification leads to a quartic equation in $\tilde{\sigma}$ (ref. 8). (An algebraic error in an earlier analysis for isothermal stratification 9 resulted in a quartic rather than a cubic equation.)

Inspection of the discriminant of equation (1) shows that increase of ε (the ratio of the dynamical to the radiative timescale) leads to a decrease of the growth rate for a tube which is convectively unstable at $\varepsilon = 0$. This decrease continues until $\tilde{\sigma}$ acquires an imaginary part, when the discriminant vanishes. It can also be seen, by examining the terms of leading power in ε (for $\varepsilon > 1$) in the expression for the real part of $\tilde{\sigma}$, that the growth rate tends asymptotically to a constant value.

What are the implications of the above results for solar flux tubes? A straightforward inference is the inhibition by radiation of convective collapse of the tubes. Increase of ε implies decrease of r_0 for a given diffusivity χ . Thus, thinner tubes will

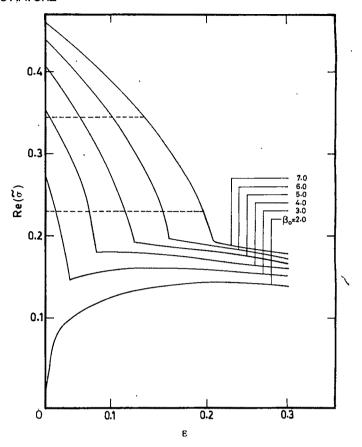

Fig. 1 Plot of Re $(\tilde{\sigma})$ against ε for different values of β_0 . Dashed lines at Re $(\tilde{\sigma})$ = 0.345 and 0.230 correspond to flux-tube lifetimes of 10 and 15 min, respectively.

collapse to a lesser extent than thicker ones. We shall now examine this phenomenon in a more quantitative manner, without forgetting the simplifications inherent in the assumption of isothermal stratification. We choose Λ_0 corresponding to 10^4 K (representing the region of largest convective instability due to hydrogen ionization), $\gamma=0.7$ (to yield a very high superadiabaticity of ~ 0.4) and d=1,200 km, assuring a stable tube at $\beta_0 \simeq 2.0$ for $\varepsilon=0$. With this choice of parameters, Fig. 1 shows the real part of $\tilde{\sigma}$ as a function of ε for different values of β_0 . We assign a value $\beta_0=7.0$ for the equipartition field of 700 G, so that $\beta_0=2.0$ corresponds to kilogauss intensity. Notice the curious cusps in the curves, which correspond to the transition from purely growing modes to overstable modes.

In the Sun, the flux tubes are presumably jostled around, with frequent rearrangement of the field lines into different concentrations 10,11 . Thus, a given tube probably exists as a separate identity for a finite lifetime, dictated externally by its environment. Tubes with growth times larger than such externally dictated lifetimes can therefore be considered as 'stable'. In Fig. 1, two horizontal lines (dashed) are drawn at $Re(\tilde{\sigma}) = 0.345$ and 0.230. These correspond to stable tubes with lifetimes of 10 and 15 min, respectively.

The 10-min timescale is representative of the normal granulation which rearranges the field lines 10, whereas the 15-min timescale represents the facular granules 12. From the intersection of these horizontal lines with the curves for different values of β_0 (Fig. 1), one can construct a plot of ε versus β_0 , showing the demarcation of stable and unstable regimes in $\varepsilon - \beta_0$ space. By choosing $\chi = 10^{10}$ cm² s⁻¹ (consistent with the solar value at 10^4 K)¹³ and assuming magnetic flux conservation as well as depth-independent β_0 for the tube, one can write the photospheric radius of the tube as $r_{\rm ph} = (p_{\rm ion}/p_{\rm ph})^{1/4} \cdot (4\tau_{\rm D}/\varepsilon)^{1/2}$ km, where $p_{\rm ion}/p_{\rm ph}$ is the ratio of the pressure at 10^4 K to photo-

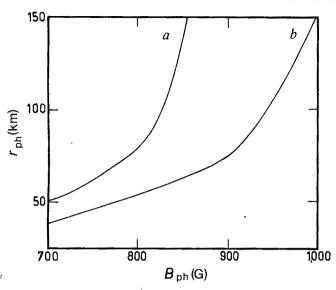

Fig. 2 Predicted photospheric cross-sectional radius of magnetic flux tubes as a function of their field strength, for stable tubes of lifetime 10 (a) and 15 (b) min.

spheric pressure and the dynamical timescale τ_D is expressed in seconds. Similarly, the surface magnetic field can be written as $B_{\rm ph} = 700\sqrt{8/(1+\beta_0)}$ G, remembering our assignment of $\beta_0 = 7.0$ to a 700-G tube. Figure 2 shows the resulting plot of $r_{\rm ph}$ versus $B_{\rm ph}$ for the two values of lifetime.

We conclude that stable tubes on the Sun would show a typical distribution of field strength versus size (Fig. 2). At one end of the spectrum, there would be intense kilogauss tubes with small dispersion in strength but large dispersion in size. At the other extreme of the distribution, there would be a group of thin tubes of fairly constant size but with a continuous distribution of field strengths ranging from kilogauss levels down to equipartition values of 700 G. The tubes observed until now from ground-based telescopes¹⁴ have perhaps belonged only to the stronger variety; observations from the new space-based telescopes should reveal the existence of the tubes at the thin end of the spectrum. A further prediction which can be made from Fig. 2 is that longer-lived tubes of a given size are magnetically more intense.

We emphasize the simple isothermal nature of the model which led to the above predictions: for a more precise prediction of the size distribution, the flux-tube model must be improved. A stability analysis¹⁵ of such an improved model has shown a similar influence of the radiative diffusion on the convective collapse, although the instability was not examined in the ε - β_0 plane as we have done here. Finally, it must be remembered that mechanisms other than convective interaction might create strong tubes below the photosphere, which could emerge above the surface by buoyancy. In this case, the curves in Fig. 2 should be taken as the stable limit of the weakest field for a given size, or conversely the limit of the largest tube of a given strength. Thus, curves like these can be used to distinguish between tubes concentrated by convection and those formed otherwise.

I thank Dr B. Roberts for comments.

Lake acidification and the land-use hypothesis: a mid-post-glacial analogue

Vivienne J. Jones, Anthony C. Stevenson & Richard W. Battarbee

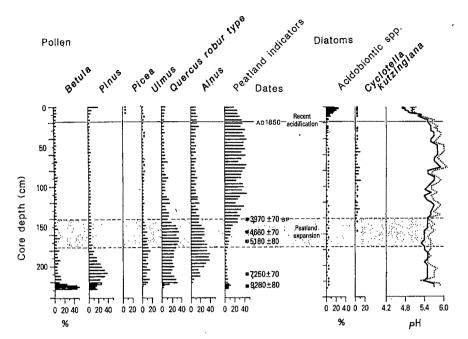

Palaeoecology Research Unit, Department of Geography, University College London, 26 Bedford Way, London WC1H 0AP, UK

It has been suggested that the recent acidification of lakes owes more to catchment soil acidification than to acid deposition. This can be tested by assessing the effect of catchment soil changes on lake acidity during earlier periods of post-glacial time, when acid deposition can be assumed to have been minimal. In the United Kingdom the mid-post-glacial formation of blanket mires in the catchments of lakes senstive to acidification provides a suitable analogue. Here we use the results of a pollen and diatom study of a sediment core from a recently acidified lake in Galloway, south-west Scotland³, to show that the lake was acid (pH 5.5-6.0) before peat formation and that no acidification occurred while peat was developing in the catchment. Acidification to pH values <5 occurs only after AD 1850, during the period of increasing acid emissions from fossil fuel combustion. We conclude that soil acidification is not the likely cause of the very low pH values found in many acidified lakes today.

Many lakes in Europe and North America have been acidified in recent decades³⁻⁸; however, arguments persist over the possible causes of acidification. Rosenquist¹, supported by Krug and Frink², has argued that the increase in the quantity of raw humus in lake catchments as a result of land-use change is of primary importance, and Pennington⁹ has attempted to illustrate this process by reference to the post-glacial development of acid lakes in the English Lake District. On the other hand, Seip¹⁰ has explained how sulphate anions from acid precipitation can carry H+ from soils with low acid-neutralizing capacity into surface waters, and Battarbee et al. 11 have used palaeolimnological techniques to show that an increase in acid deposition is the only plausible hypothesis to explain the acidification of Galloway lakes with non-afforested catchments, partly by showing that a land-use change as postulated by Rosenquist has not occurred in this region.

Although there is theoretical support and empirical evidence for both mechanisms of surface water acidification, we would like to know which is more important in the recent acidification of lakes in areas where both processes have been occurring2. Palaeoecological techniques can be used to separate these factors by considering the influence of catchment changes on a lake at a time when sulphur emissions from industrial sources can be assumed to have been minimal. Such time controls are superior to spatial controls because they allow us to study lakes in areas of high acid deposition, which have already been shown to be recently acidified. Moreover, many important variables such as lake morphometry and the ratio of catchment to lake area can be held constant. Suitable pre-industrial sites and time periods can be identified by pollen analysis and 14C dating.

In the United Kingdom the mid-post-glacial expansion of blanket mire vegetation in upland areas provides the ideal test situation. The replacement of forest vegetation by Calluna heathland and the leaching and paludification of mineral soils to create acid peatland environments has been well established

Fig. 1 Composite pollen and diatom diagram for a core from the Round Loch of Glenhead. including ²¹⁰Pb and ¹⁴C dates and pH reconstruction based on Index B (refs 5, 19) and multiple regression of pH preference groups11 Peatland indicators are Calluna vulgaris, Sphagnum, Cyperaceae, Succisa and Potentilla; acidobiontic spp. are Tabellaria quadriseptata, T. binalis and Navicula hofleri. Solid line, Index B (Galloway); dotted line, multiple regression.

by palaeoecologists 12,13. Blanket mires of this kind dominate the catchments of lakes in Galloway which have been strongly acidified since 18503. For one of these sites, Round Loch of Glenhead, we have carried out pollen analysis and ¹⁴C dating of a complete post-glacial sediment core to identify and date the development of blanket mire in the area, and we have used diatom analysis to reconstruct the pH history of the loch before, during and after the catchment change.

Pollen data from Round Loch (Fig. 1) show a complete early post-glacial forest succession from Betula-Pinus (9,280± 80 yr BP at 223-227 cm, Fig. 1) to Pinus-Ulmus-Quercus, and then to Quercus-Ulmus-Alnus woodland (7,250 ± 70 yr BP at 208-213 cm, Fig. 1). The woodland was subsequently replaced by an acid peatland dominated by Calluna, Cyperaceae and Sphagnum between 6,000 and 4,000 vr BP. Following this, few changes occurred until the recent afforestation in the region in the past 30 yr, indicated by the increased Pinus and Picea values in the uppermost sediment (Fig. 1). A detailed pollen stratigraphic examination of the catchment peatland (V.J.J., unpublished data) confirms that the pollen changes in the lake core reflect changes in the local region, and ¹⁴C dates for the inception of peat formation in the catchment indicate that acid organic soils were gradually replacing mineral soils and covering exposed bedrock from 9,000 yr BP onwards.

In spite of the early development of acid soils, the diatom record (Fig. 1) shows that neither this nor the later expansion of blanket peats caused an acidification of the lake. On the contrary, at the time of blanket mire expansion there was an increase in Cyclotella kutzingiana, a planktonic species that is rarely found in any abundance below $pH \sim 5.5$, and an increase in Fragilaria virescens, a species with circum-neutral pH preference. These changes indicate a small but significant increase in mean water pH, reflected in the pH reconstruction (Fig. 1), and suggest that leaching of sub-soil mineral horizons by more acidic soil water was responsible for an increase in alkalinity of the lake water. In general, the data show that Round Loch had a pH between ~5.5 and 6.0 throughout the post-glacial period, until the recent post-1850 acidification, when pH fell by almost one unit to the present value of \sim 4.7.

Previous studies of long-term lake acidification in the United Kingdom¹⁴⁻¹⁸ appear to be in conflict with these findings, as they all show an acidification trend during the early millennia of the post-glacial period. However, in none of these cases was

the early post-glacial diatom flora as acid as at the Round Loch. probably because none was situated on granitic bedrock, and in all cases the post-glacial acidification trends did not result in a diatom flora characteristic of acid lakes (that is, with negative alkalinity). These data are therefore consistent in showing that nowhere did soil acidification and blanket mire formation during the post-glacial period result in the lowering of lake water pH below $\sim 5.0-5.5$.

Soil acidification does not necessarily lead to surface-water acidification, especially where surface waters have low alkalinity and where acids generated in organic horizons can be neutralized by cation exchange and weathering in mineral horizons. Results from the studies cited above 14-18 show that acidification of lakes from alkaline to slightly acid conditions has occurred during the early post-glacial period, probably as a result of catchment soil changes. The Round Loch data, however, indicate that soil acidification is not a sufficiently effective mechanism to explain the very high levels of acidity found in contemporary acidified lakes. The hypothesis can be rejected in Galloway and must be open to serious question in other regions.

This work was carried out while V.J.J. was supported by a. NERC research studentship. We thank D. Harkness (East Kilbride) for ¹⁴C dates, and R. S. Clymo, S. J. Phethean, R. J. Flower, S. T. Patrick, N. J. Anderson and P. Raven for help with fieldwork. John Theaker and his NCC staff kindly transported our equipment to the site.

Non-axisymmetric behaviour of Olduvai and Jaramillo polarity transitions recorded in north-central Pacific deep-sea sediments

Emilio Herrero-Bervera* & Fritz Theyer†

* Hawaii Institute of Geophysics, University of Hawaii, 2525 Correa Road, Honolulu, Hawaii 96822, USA † Department of Geological Sciences, University of Southern California, University Park, Los Angeles, California 90089, USA

The causes of the reversals of the Earth's magnetic field can be investigated by studying the palaeomagnetic record preserved in rocks. A proper documentation of reversal phenomena should yield valuable information about the generation of the field. Deep-sea sediments provide a globally and temporally distributed set of polarity transition records. Our studies²⁻⁴ of the Olduvai (1.88-1.72 Myr)¹ and Jaramillo (0.94-0.88 Myr)¹ subchrons using deepsea sediments showed that the time-averaged behaviour of the geomagnetic field during these reversals proved to be reliably recorded, independent of the latitude and longitude of the sample site. Here we test some phenomenological transition models and present directional data, virtual geomagnetic poles (VGPs) and related directions in rotated declination, inclination (D', I') space⁵, using two records of the Olduvai reverse-normal-reverse (R-N-R) and two records of the Jaramillo R-N-R polarity transitions. These data are better explained by the flooding rather than the standing field model, but they also indicate a degree of asymmetry of the transitional field.

The palaeomagnetic data presented here are associated with a pair of sequential reversals (R-N and N-R) from a fully azimuthally-oriented piston core^{2,6,7} (K78030; 18°55.9' N, 160°70.8' W) taken near the Hawaiian island of Kauai. The other two records are from two other fully azimuthally-oriented piston cores^{2,6,7}: K76113 from low latitude (2°40.1' N, 178°45.1' W) and K7501 from a mid-latitude site (37°22.4' N, 179°36.1' W), which encompass the Olduvai reversals (R-N, K76113 and N-R, K7501).

The transitions studied were sampled using a 'high-resolution' technique²⁻⁴. The measurements derived from each sample represent a signal averaged from as little as 200 to as much as 1,000 years of post-depositional remanent magnetization (PDRM) history (considering the sediment accumulation rates of the cores studied). Thus, with a typical 3-mm offset between boxes, field fluctuations of periods between 200 and 600 years should, at least theoretically, be within the reach of our high-resolution technique. The four records discussed here are characterized by high palaeomagnetic stability of the samples within and outside the transition zones²⁻⁴.

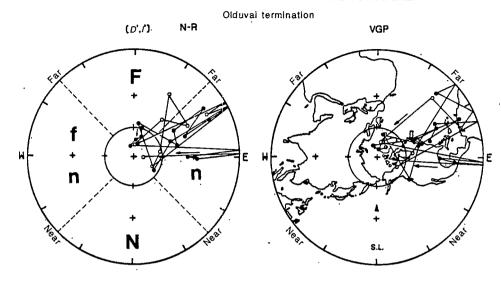

Figures 1 and 2 show the highly detailed VGP paths associated with the two sets of transitions. The VGPs are plotted with respect to their site longitude⁵ and are those which represent intermediate directions, as well as some outside the transition zones. The pattern of change in field directions is clear for the two transitional sets (Olduvai and Jaramillo subchrons) and is sufficient to apply Hoffman's8 test (to distinguish between the flooding model and the existence of a stationary (non-reversing) portion of the field during axial dipole decay and regeneration, using palaeomagnetic data corresponding to back-to-back (R-N and N-R) polarity transitions). During the onset of the Olduvai subchron R-N transition (core K76113), the VGPs representing the field remain southerly while migrating to nearly equatorial latitudes. The ancient field apparently underwent a rapid set of 'flips' during the transition, like those observed in several other detailed records^{9,10}. From the southerly latitudes, the VGPs migrate up to the Northern Hemisphere to the expected normal field direction. The path is clearly near-sided and is longitudinally confined. In the N-R reversal (core K7501) at the termination of the Olduvai subchron, a different sequence is observed. The termination path is more complicated than the onset path and is characterized by more intermediate VGPs (fewer in the Southern Hemisphere with respect to the VGPs in the Northern Hemisphere) and bigger loops in its traverse from northern latitudes to southern latitudes. These loops may show rapid fluctuations of the transitional field. The path can be classified as a far-sided path even though some of the VGPs he in the near-sided section of the plot (±90° from the site longitude). This path also exhibits a longitudinal confinement, as does the onset transitional path. Thus, both reversals are characterized by transitional VGP paths which lie along meridional bands on either side of the 90° meridian, but the paths are not completely antipodal.

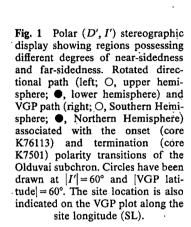

Analysis of the two Jaramillo transitional paths recorded by core K78030 (Fig. 2) shows that the two paths are dissimilar even though they represent records of a back-to-back transition zone from the same site. For instance, the R-N records display intermediate VGPs lingering at low southerly latitudes in the vicinity of the 90° meridian, with a sudden transit to the Northern Hemisphere where big loops occur before the final move to the expected normal direction. The path could be classified as near-sided because most of the intermediate VGPs reside within ±90° of the site longitude. The N-R Jaramillo transition path is more complicated than the R-N Jaramillo path. The VGPs in the Northern Hemisphere linger briefly before their transit to southern latitudes where they seem to migrate, forming loops in the Southern Hemisphere before their final move to the expected reversed field direction. This path is hard to classify as near-sided or far-sided because the VGPs lie on both sides of the meridian 90° from the site longitude. Thus, the transitional field of these two reversals was different. A characteristic of both the Olduvai sets and the Jaramillo sets is that the paths are not antipodal. A comparison of all four paths—between sites and within sites—shows that they are characterized by individual features peculiar to each transition; and overall, the data indicate that the reversal process is asymmetric, such that each reversal sense is associated with a different field configur-

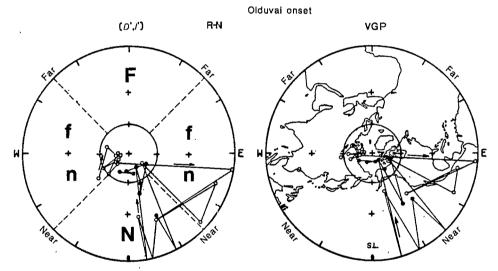

Figure 1 shows the VGP data, as well as the transition data rotated using Hoffman's method⁵. The polar (D', I') stereographic plot clearly shows that at the onset of the Olduvai subchron (K76113) the field displays an initial near-sided vector movement in quadrant 'n' (the first 10 rotated directions which are apparently closer to the reversed polarity and which represent the initiation of the reversal—still not part of the transitional field); then, a swing to the other quadrant 'n'; and finally a movement to normal polarity in the 'N' region of the diagram. These last two steps are part of the strictly transitional field behaviour. Thus, from this record alone, it can be concluded that the field geometry during the onset of the Olduvai reversal is consistent, but not uniquely so, with a hypothesized transi-

Table 1 Results of rotated intermediate directions and VGPs of Olduvai and Jaramillo polarity transitions

Onset	R-N	n-f	N
K78030			
Olduvai			
Termination	N-R	f	f
K7501			
Onset	R-N	n-N	n-N
K76113			

tional palaeofield geometry which is significantly zonal (rotated directions in the 'N' region of the (D', I') diagram), as well as a non-axisymmetric palaeofield geometry (rotated transitional directions in the 'n' region). Figure 1 also shows the transitional characteristics of the termination of the Olduvai subchron (core K7501). The record displaying the rotated (D', I') directions shows that the path lies on the far-side region of the polar diagrams. Initially, the reversal is controlled by a consistent axisymmetry, and during the middle and final stage of the reversal the field was apparently dominated by non-axisymmetric terms; most of the rotated directions are located in the 'f' region.

The two transitional records (Olduvai reversals) present entirely dissimilar characteristics. For instance, the rotated directions of the R-N reversal record are near-sided, whereas the rotated directions of the N-R record are far-sided. The two records do not present antipodal directions; instead, at different stages of the reversals some of the directions are consistent with a dominating axisymmetry and others with non-axisymmetric terms.

The rotated directions and VGP paths for the two back-to-back reversal records of the Jaramillo subchron (core K78030, from \sim 300 km from Kauai) are shown in Fig. 2. The (D', I') rotated directions of the R-N reversal record of the Jaramillo subchron display almost a total dominance of a consistent axisymmetry.

Such rotated directions are located in the 'N' region of the polar diagram. This reversal record shows that at the initial stage of the transition some of the directions are located on the far side of the polar diagram, and at some stage two directions are in the 'n' quadrant. Nevertheless, the path could be classified as near-sided. Figure 2 also shows the N-R reversal path of the Jaramillo subchron. This is a unique path with respect to the other three paths presented here: it is more complex than the R-N Jaramillo path and displays rotated directions on both the near and far side of the polar diagram. One group of rotated directions is in close proximity to the $D' = 90^{\circ}$ great circle (that is, the plane containing the horizontal east-west line and the axial dipole field direction). Other groups of directions are along the $D' = 180^{\circ}$ great circle (the plane containing the north-south line and the axial dipole field direction). In general, this transitional record is characterized by stages of the reversal that are in the 'N', 'n' and 'f' regions of the polar projection plot, although the path lingers mostly in the far-sided region of the diagram.

Each of the records presents individual characteristics, perhaps indicating that the harmonic content of each is different, even in the case of the two records of the Jaramillo subchron taken from the same core³. From a study of two older (Pliocene) Kauai back-to-back reversal records, Bogue and Coe concluded that those two paths are distinctly near-sided¹⁰⁻¹². Our nearby

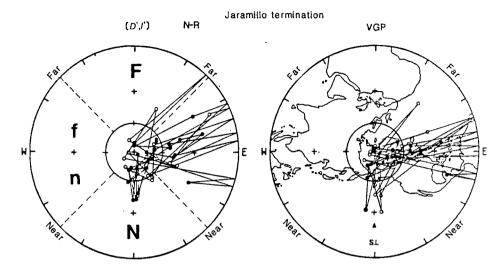

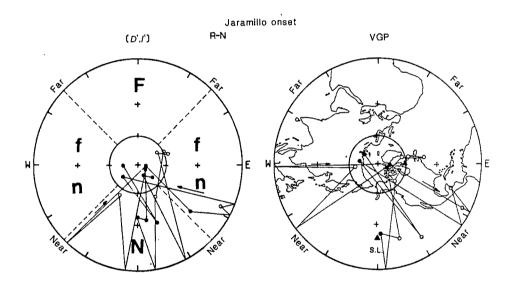

Fig. 2 Polar (D', I') stereographic display showing regions possessing different degrees of near-sidedness and far-sidedness. Rotated directional path (left) and VGP path (right) associated with the onset and termination polarity transitions of the Jaramillo subchron (core K78030). Circles have been drawn at $|I'| = 60^{\circ}$ and |VGP| latitude |VGP| at the site location is also indicated on the VGP plot along the site longitude (SL). Symbols as in Fig. 1.

core (K78030) that recorded the Jaramillo back-to-back reversals indicate that the R-N record is near-sided, whereas the N-R record is classified as a far-sided path using Hoffman's terminology. However, certain common characteristics must be taken into consideration. One is the site dependence of the transitions: the two R-N reversal records are near-sided and the two N-R reversal records are far-sided, or at least most of the rotated directions are on the far side of the diagram (for example, Olduvai termination). All four transition records show intermediate rotated directions residing in regions 'n' and 'f' that are only marginally near- and far-sided respectively (see Table 1). All four records are unambiguously associated with significantly non-axisymmetric transitional fields. Another common feature of these paths is that all tend to reside on the American continent. As shown in Figs 1 and 2, the VGP paths are clustered about the 90° meridian. This area is also where the VGP paths from Crete are located¹³.

Which of the current models for transitional field behaviour explains the characteristics of the Olduvai and Jaramillo records discussed here, the standing field model¹⁴⁻¹⁶ or the flooding model^{17,18}? The former predicts identical transitional field behaviour for repeated reversals as observed from a single site, and requires the postulated standing field to persist for several million years, whereas the latter treats the Earth's fluid core as a distributed source of magnetic field in which polarity transi-

tions begin with a localized reversal of field sign in a small region of the core, an effect that consequently spreads or floods through the rest of the source region. If the reversal starts at either of the poles or at the equatorial zone of the core, basically axial quadrupolar, or axial octupolar fields, respectively, will predominate during the intermediate stages of the reversal process. For the purely axisymmetric, and consequently the simplest cases, the flooding will begin at a pole (a predominantly quadrupolar transitional field) or along the equatorial band of the fluid core (an octupolar field at the midpoint of the reversal). Depending on the sense of the reversal and the hemisphere of the observer, the VGP path will be near-sided (same longitude as the site) or far-sided (180° away from the site). This is the basis of Hoffman and Fuller's method¹⁹ for determining the origin point of flooding, which involves the comparison of palaeomagnetic records of both R-N and N-R reversals.

The standing field model cannot successfully explain the diverging behaviour of the paths because it predicts identical transitional field behaviour for repeated reversals when viewed from a single site. Moreover, Bogue and Coe¹¹ have shown that the palaeointensity records of the Kauai transitions are not consistent with the standing field model. The same conclusion was reached by a palaeointensity study of the Steens Mountain polarity transition²⁰.

The generalized flooding model can successfully explain these data. For the two successive reversals (Jaramillo subchron), the model predicts (so long as a reversal is initiated at the same zone in the core each time) transitional VGP paths that differ in longitude by 180°. In general, for core K78030 the two records are not antipodal (R-N near-sided and N-R far-sided), and the same conclusion can be drawn from the Olduvai subchron paths, even though the two records are from two different localities. The salient directional features shared by all of these records are the overall longitudinal confinement of most intermediate VGPs and respective rotated directions well to the east of the sites; and the typical location of the intermediate VGPs over the Americas, the southeastern Pacific and the western Atlantic. None shows smooth pole-to-pole paths; all define major loops (including east-west swings, for example, in the Olduvai onset record, Fig. 2) before settling into the expected opposite polar positions. The important issue here is that the VGP paths are not antipodal. The rotated directions of all these data prove that the reversal process is asymmetric, such that each transition sense is associated with a different field configuration. Indications that the flooding process is itself asymmetric have been recently reported from the studies of the Kauai and Steens Mountain transitions 11,20

Late Palaeozoic to early Mesozoic evolution of Pangaea

R. A. Livermore*, A. G. Smith* & F. J. Vine†

* Department of Earth Sciences, University of Cambridge, Downing Street, Cambridge CB2 3EQ, UK

† School of Environmental Sciences, University of East Anglia, Norwich NR4 7TJ, UK

Several possible configurations of the Pangaea supercontinent have been suggested for the interval from late Carboniferous to early Triassic. Here we re-examine the palaeomagnetic basis for these models, emphasizing the trends of the paths of apparent polar wander for the individual components of the supercontinent rather than simply averaging poles of presumed similar age. Two of the alternatives, Pangaea B and C, may result from averaging poles of dissimilar age along common polar wander paths, giving rise to spurious tectonic displacements. The most likely model appears to be the formation, in late Devonian time, of a modified Pangaea (A2) followed by evolution to the traditional configuration (A) during the Triassic.

Hallam¹ reviewed geological information concerning the possible configuration of the Pangaea supercontinent in Permo-Carboniferous time and concluded that the evidence favours an unchanged configuration from the late Carboniferous to the Jurassic. However, the palaeomagnetic data disagree with such a model. In particular, late Palaeozoic poles from Gondwanaland are distinct from those obtained for the northern continents when plotted on the 'traditional' Pangaea reconstruction. Solutions to this problem range from an anticlockwise rotation of Laurasia relative to Pangaea of ~20° about a pole in the western Sahara²⁻⁵, to a rather larger rotation of $\sim 35^{\circ}$ about a different pole⁶⁻¹¹, to a drastic model in which northwestern South American is juxtaposed with southern Europe¹². These solutions have been designated Pangaea-A2, Pangaea-B and Pangaea-C respectively^{1,10}. Figure 1 shows the alternative reconstructions for the Permian, plotted on the same scale and in palaeomagnetic

Most of the contrasts between the competing models are due to differences in palaeolongitude of the component fragments: thus, palaeomagnetic data from a restricted interval of geological time cannot easily distinguish between these alternatives. However, a careful examination of the apparent polar wander paths of the component continental blocks for a longer period of time may allow some of the models to be discounted. This is the approach we have followed in our re-evaluation of the palaeomagnetic data.

Carefully selected palaeomagnetic poles from the interval 180-320 Myr (ref. 13) have been returned to their palaeogeographical positions in the alternative reconstructions. The data have then been sampled in 20-Myr non-overlapping windows and Fisher statistics calculated for the various continental fragments in an attempt to examine the implications of the various models.

The poles were selected from recent lists of data thought to represent the ancient geomagnetic field direction, such as those given by Embleton¹⁴ for Australia and East Antarctica, by Van der Voo15 for North America, and by Brock16 for Africa and Madagascar. In addition, more recent results (to 1983) have been incorporated. Results for which the time of magnetization could not be estimated to within 25 Myr were excluded. All the poles used conform to the minimum reliability criteria of McElhinny¹⁷ and are based on studies in which AF (alternating-field) and/or thermal cleaning techniques were employed. Results from within or east of the Urals have not been included because of the likelihood of relative motions between Europe and Siberia during at least part of the period of interest. Stratigraphic ages have been referred to the timescale of Harland et al. 18 and K-Ar dates have been standardized to the decay constants given by Steiger and Jaeger¹⁹. The assigned ages, together with the absence of Russian data and the inclusion of some more recent studies, constitute the chief differences between this dataset and that used by Morel and Irving¹⁰.

Any time window for data grouping must be narrow enough to preserve the main features of apparent polar wander (APW) paths, yet broad enough to allow sufficient poles to be included to define precise means. A width of 20 Myr was chosen as the minimum presently permitted by the number and quality of available data. Having returned the poles to the various reconstructions, Fisher statistics were calculated in Africa-fixed coordinates for each continent within each window, assuming a geocentric axial dipole field. The means and their associated A₆₃ standard error circles are given in Table 1 for the four

Fig. 1 Alternative models of the Pangaea supercontinent, orientated using early Permian (270 Myr) palaeomagnetic data. Orthographic projection. a, Pangaea-A, constructed using published sources²⁶⁻³¹: this is comparable to the classic reconstructions of Wegener³² and Bullard et al.³³. b, Pangaea-A2 reconstruction, obtained by applying an additional rotation of 20° about a pole in the north-west Sahara to Laurentia-Baltica, after ref. 2. c, Pangaea-B reconstruction, obtained using the rotations of Irving¹¹ for Laurentia, Baltica and Gondwana. d, Pangaea-C of Smith et al.¹², showing a large Tethyan offset of Gondwana and the northern continents of several thousand kilometres.

^{*} N is the number of poles averaged to obtain the mean pole for an interval.

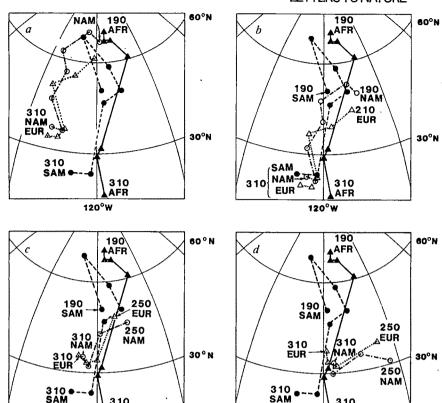

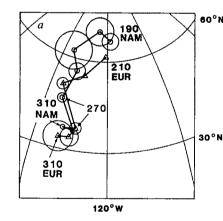

Fig. 2 Positions of mean palaeopoles and standard error (A_{63}) circles relative to an Africa-fixed Pangaea-A reconstruction, showing the general agreement of trends. However, detailed examination reveals differences in timing; for example, the 270-Myr means for Europe and North America disagree, as do those for South America and Africa. Lambert Equal Area projection. a, North America (\bigcirc) and Europe (\triangle) . b, South America (\bigcirc) and Africa (\triangle) .

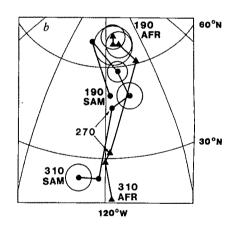

Fig. 3 a, APW paths of the northern (North American, European) and southern (African, South American) continents plotted relative to Pangaea-A in Africa-fixed coordinates. Symbols as for Fig. 2. Equal area projection. b, As for a but plotted relative to Pangaea-A2. The discrepancy between northern and southern continents before 210 Myr is now reduced, although the timing of motion along the common path varies between continents. c, As for a, but plotted relative to Pangaea-B for the interval 250-310 Myr. d, As for c, but plotted relative to Pangaea-C.

models. Note that no results are given for times younger than 250 Myr for either B or C, as these models were only intended for Permo-Carboniferous time.

Figure 2 illustrates the poles calculated with respect to Pangaea-A. Figure 2a shows that the trends of the APW paths for Europe and North America, especially for pre-Triassic time for which more reliable data are available, are very similar. Apart from the oldest two intervals, however, the A_{63} circles do not overlap and there is a clear offset in age along the common path. On the other hand, there is good agreement between the 290-, 270- and 250-Myr poles from North America and the 270-, 250- and 230-Myr poles for Europe, respectively. This suggests a possible error in intercontinental correlation of up to 20 Myr, or widespread remagnetization of the North America formations after a similar period of time. Similarly, although less obviously, the paths for South America and Africa (Fig. 2b) follow broadly similar northward routes, but with quite large divergences for individual windows, for example, 260-280 Myr.

Part of these differences may be attributable to dating errors for individual results, coupled with rapid polar wander. The discrepancies do appear to be systematic, however, and one suspects that a more fundamental problem exists concerning the accuracy of the stratigraphic correlations on which most of the assigned ages are based. In addition, many poles derive from studies of non-fossiliferous red sediments, for which the mechanism of remanence acquisition remains to be clearly demonstrated.

The observed differences cast considerable doubt on the Pangaea-B and -C reconstructions, because both of these models were constructed by moving Laurasia and Gondwanaland until their Permian and late Carboniferous poles coincided. If there are systematic errors in the correlation of these poles, then these reconstructions may be viewed as artefacts of the dating errors. An example of this may be seen in the Pangaea-B model, which requires a small ocean separating Europe and North America to satisfy an observed difference between their mean palaeopoles¹⁰. If, as suspected, this difference arises from dating errors along a common polar wander path, then no such separation (for which geological evidence is absent) is required.

One conclusion that can be drawn from the foregoing is that comparison of APW path segments is to be preferred to the simple averaging of supposedly contemporaneous poles. Figure 3 shows the polar wander paths for the four main continents (North America, Europe, Africa and South America) plotted with respect to Pangaea-A, A2, B and C in Africa-fixed coordinates. Figure 3a, b clearly illustrates the discrepancy between the paths for the northern and southern continents in the Pangaea-A reconstruction for times before 210 Myr, and the improvement for this time interval obtained if one assumes Pangaea-A2.

In Fig. 3c, d the paths are superimposed for reconstructions B and C, respectively, but only for the period 310-250 Myr, because it is only for this earlier period that these reconstructions have been suggested. With the exception of Pangaea-B for a period of time centred on 270 Myr, there is little similarity between the polar wander paths for the northern and southern continents in either reconstruction. We stop short of suggesting an evolution A2 to B to A2 to A, which would imply implausibly high rates of plate motion, and on the basis of the comparison of APW paths consider it unlikely that Pangaea ever existed in the form of configuration B or C.

It now seems clear from palaeomagnetic, biogeographical and stratigraphic evidence that the configuration of Pangaea immediately before its disruption was similar to that portrayed in Fig. 1a. For earlier times, uncertainty remains. There is doubt about the precise timing of the final collision between Gondwanaland and Euramerica which brought Pangaea into being. Depending on the interpretation of Devonian palaeopoles from Gondwana, this collision may have occurred either during the early Carboniferous or as early as late Devonian²⁰. The exact configuration at these times is not known with certainty, but published reconstructions favour Pangaea-A221,22

Several workers^{3,5} have noted the close agreement between the fossil faunas and tectonic structures of southern North America (such as the Oachita and Marathon belts) and those of northern South America (such as the Venezuelan Andes), and have suggested that better alignment of similar provinces can be achieved when the tighter A2 fit is adopted. If an A2 to A transition is accepted, the geological problem is that of locating the structures along which the transition took place, and determining their nature and displacement. A suitable zone of transcurrent motion is most plausibly located along part of the present-day continental margins of eastern North America and north-west Africa. To accommodate such motion in a simple fashion, the Euler pole for A2 would need to be modified, as it does not agree in detail with such a transition zone. This subject will be dealt with elsewhere.

The notable Permo-Triassic volcanism of the Alpine region sensu lato, interpreted as representing the break-up of the region, was followed by the subsidence of huge late Triassic and early Jurassic carbonate platforms, whose creation pre-dates the Pangaea^{23,24}. The Alpine cycle began in Triassic or possibly Permian time, but the Atlantic Ocean did not begin to open until the middle Jurassic. The observed tectonic pattern might well reflect mid- to late-Triassic plate margins formed by the A2 to A transition.

In view of this discussion of polar wander paths, and the geological arguments advanced by Hallam¹, both Pangaea-B and Pangaea-C seem less likely candidates, possibly resulting from uncertainties in the dating of components of remanence and/or intercontinental stratigraphical correlation. The most probable evolution appears to be formation of a supercontinent resembling Pangaea-A2 during the late Devonian21, followed by Permo-Triassic readjustments involving dextral shear, and the reorganization of fragments in the Gulf of Mexico and Mediterranean regions. This was accompanied by rapid motion of all the major continents with respect to the poles. Siberia and the Asian components of Pangaea (Kazakhstan, China, and so forth) were probably sutured to Europe during Permo-Triassic time¹⁷. By the late Triassic, Pangaea-A was in existence, and, although probably undergoing extension in early Jurassic time, remained intact as a supercontinent until break-up in the middle Jurassic²⁵.

This work was funded by a NERC studentship and grant number GR3/4405. This is Cambridge Earth Sciences contribution 761.

The islands of San Felix, San Ambrosio and the Juan Fernandez group comprise one of the few subaerial occurrences of intraplate oceanic volcanism between the Mid-Atlantic Ridge and the East Pacific Rise south of 20°S, and are therefore valuable in the assessment of large-scale geochemical heterogeneities in the Earth's mantle 1-3. We present here the results of a preliminary Sr, Nd and Pb iosotpic study of basic lavas from these islands. All samples show a moderate Dupal³ signature (anomalous Sr. Nd and Pb isotopic compositions). Basalts from the Juan Fernandez group lie close to the mantle plane4, whereas basalts from San Felix display unusual isotopic characteristics which plot well below the Nd-Sr oceanic array. Based on this data, we propose the delineation of a new mantle array, linear in Nd-Sr-Pb isotopic space, with Tubuaii and Walvis Ridge as end members. The mixing relationships exhibited by this array suggest that both end members are geographically contiguous, and probably reside in delaminated sub-continental lithosphere.

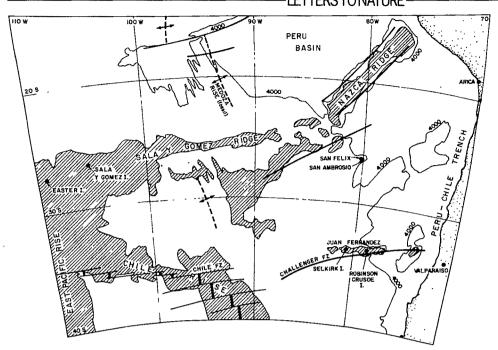

Fig. 1 Generalized tectonic map of the South-East Pacific, showing the location of San Felix, San Ambrosio Juan Fernandez islands (modified from ref. 42). Shaded areas represent depths less than 3,500 m; 4,000 m contours are also shown. Dashed lines represent extinct spreading ridges. San Felix and San Ambrosio are not related to present or older spreading systems or fracture zones, nor is there any convincing older hot-spot trace extending to the east from these islands. The Juan Fernandez islands lie along an eastwest-trending bathymetric ridge, probably associated with the Challenger fracture zone; this ridge may represent a hot-spot trace, as some bathymetric expression can be traced up to 500 km eastwards. Robinson Crusoe island lies on ~38-Myr-old crust; San Felix and San Ambrosio lie on ~42-Myr-old crust.

The Juan Fernandez islands are located on a N80° E-trending aseismic ridge, the Juan Fernandez Ridge, whereas San Felix and San Ambrosio do not appear to be associated with any significant tectonic or topographic feature (Fig. 1). San Felix and San Ambrosio (26°25′ S, 79°59′ W) are small (<3-4 km²), and located 20 km apart; although no historic eruptions have been reported, fresh-looking pahoehoe lava flows and fumarole activity on San Felix were observed by Willis and Washington⁵. These islands are mainly platforms bounded by steep cliffs, and consist largely of interbedded lavas and deeply weathered pyroclastics intruded by dikes⁵.

166

The Juan Fernandez islands include one large island, Robinson Crusoe (~50 km², at 33°37′ S, 78°50′ W), a much smaller nearby islet, Santa Clara, and A. Selkirk Island, 200 km to the west. Robinson Crusoe island is heavily eroded, with no historic record of volcanic activity, although evidence of submarine volcanism immediately west of Robinson Crusoe has been reported^{6,7}. An extensive volcanic sequence of >2,200 m thickness is exposed on Robinson Crusoe island⁸. The lowest unit (Punta Larga, >800 m thick) consists of extensive basalt flows with rare interbedded pyroclastics. The middle unit (Puerto

Ingles, \sim 1,200 m) consists of olivine-phyric to picritic basalts interbedded with a relatively greater proportion (\sim 30%) of pyroclastics. Basalt samples from this unit have been dated by K-Ar at 3.1-3.5 Myr (ref. 9). The youngest unit (Bahia del Padre, \sim 250 m thick) is made up mainly of pyroclastics, with minor olivine basalt flows.

Samples collected from San Felix in 1923 by Willis⁵ include weathered tuff, trachyte and basanite. Of these, we chose for analysis one fresh basanite and one sample of basanite glass, occurring as small inclusions in a palagonitized basanite tuff (Table 1); a fresh tephritic basalt⁵ from San Ambrosio was also analysed. Basalts from Robinson Crusoe are transitional to alkalic, and vary in freshness and olivine phenocryst content.

The basanites from San Felix and San Ambrosio are similar in major- and trace-element composition (D. Gerlach and S. R. Hart, unpublished data) to basanites from alkalic suites of Atlantic oceanic islands such as Fernando de Noronha, St Helena and Tristan da Cunha (refs 10, 11; D. Gerlach and J. Stormer, unpublished data). The basalts of Robinson Crusoe are similar in their major- and trace-element compositions to transitional and alkalic basalts from several Hawaiian vol-

Chemical and isotopic techniques are as described elsewhere ³⁸⁻⁴⁰. SiO₂ (samples 1-10) by XRF, K₂O, Rb, Sr and Ba by isotope dilution; SiO₂ analyses of samples 11 and 12 are from ref. 5. Abundances are reported on an anhydrous basis. Sr and Nd isotope ratios are reported relative to 0.708000 for E+A standard, and 0.512640 for BCR-1; 2 σ precision refers to least significant figures. Pb isotope data corrected for fractionation, ratio by ratio, using results for NBS SRM 981; absolute values adopted for this standard (16.9373, 15.4925, 36.7054) are from ref. 41. Reproducibility of Pb ratios is better than 0.03% per AMU; in-run precision is a factor of 5 better. Samples 1, 3-7 also analysed for ⁸⁷Sr/⁸⁶Sr after HCl leaching, with identical results to above values.

^{*} Samples 1-7 are from Puerto Ingles unit, 8 and 9 from Punta Larga unit, Robinson Crusoe island (Juan Fernandez group), arranged in order of increasing age. Samples 10 and 11 are from San Felix Island; 12 is from San Ambrosio Island.

[†] A, alkali; B, basalt; O, olivine; T, transitional; Bs, basanite; Te, tephrite.

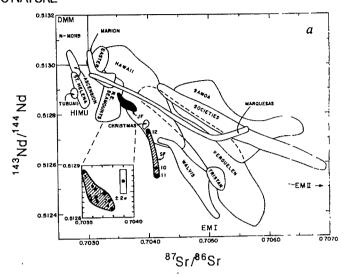

canos¹²⁻¹⁵. Alteration by weathering may have affected alkalielement abundances in some samples notably numbers 3 and 6, which are characterized by abnormally high K/Rb ratios (Table 1).

Samples from Robinson Crusoe display relatively narrow ranges in ⁸⁷Sr/⁸⁶Sr (0.70351-0.70378), ¹⁴³Nd/¹⁴⁴Nd (0.51282-0.51288) and ²⁰⁶Pb/²⁰⁴Pb (19.04-19.21) (Table 1), and lie close to the mantle plane of Zindler et al.4. The two samples from San Felix are characterized by relatively higher 87Sr/86Sr and lower ¹⁴³Nd/¹⁴⁴Nd, whereas the San Ambrosio sample is intermediate between San Felix and Robinson Crusoe (Table 1, Fig. 2a). With regard to their Pb isotopic compositions, samples from San Felix, San Ambrosio and Robinson Crusoe show a moderate Dupal signature³, with relatively high ²⁰⁷Pb/²⁰⁴Pb and ²⁰⁸Pb/²⁰⁴Pb ratios for a given ²⁰⁶Pb/²⁰⁴Pb ratio (Fig. 3). The San Felix samples plot well below the Nd-Sr mantle array, whereas basalts from Robinson Crusoe plot approximately within the mantle array, although on the low side (Fig. 2a). Other volcanic samples which plot below the Nd-Sr mantle array include basalts from St Helena¹⁶, the New England Seamounts¹⁷, Tubuaii¹⁸ and various volcanics from continental settings such as the Leucite Hills19, the Permian Oslo Rift20 and the Scottish Tertiary basalts^{21,22}.

Contamination of mantle-derived magmas at relatively shallow levels by old, granulitic crustal materials^{21,22} tends to produce similar deviations to the low side of the Nd-Sr oceanic array, but this is not a likely explanation for islands in an oceanic setting such as San Felix. Sources for oceanic islands with radiogenic Pb signatures such as San Felix and St Helena cannot have been produced by recycling of upper continental crust into the mantle, as this would displace the data along or to the right of the Nd-Sr mantle array²³ (Fig. 2a). An alternative hypothesis, similar to those of Vollmer et al.¹⁹ for the Leucite Hills volcanics and of Menzies and Wass²⁴ for the Kiama xenoliths, suggests that sources of volcanics plotting below the Sr-Nd mantle array were created during an ancient mantle enrichment event in which depleted upper mantle was metasomatized or modified by lightrare-earth-element-enriched, Rb-poor agents. In the case of islands with radiogenic Pb signatures, this metasomatizing agent would also need to have high U/Pb ratios.

The number of 'components' proposed for oceanic mantle basalt sources has steadily increased over the past few years; at least four now seem to be needed^{25,26}, and as many as five have been proposed^{2,27}. Although there is some agreement as to the isotopic signatures of these components, their identification with reservoirs of specified genesis is still controversial. The depleted upper mantle (DMM²⁶) is generally acknowledged to be the source region for mid-ocean-ridge basalts (MORB). The St Helena-type component (HIMU²⁶) is variously identified with ancient subducted oceanic crust^{4,27,28}, metasomatized mantle²⁵ or lower mantle which has lost Pb to the core²⁹⁻³¹. The other two necessary components have enriched isotopic signatures ($\varepsilon_{\rm Nd}$ < bulk earth): one, represented by the Walvis Ridge³² is called EM I²⁶; the other¹⁶, represented by Samoa and the Society islands, is called EM II²⁶ (see Fig. 2). These enriched mantle sources have been variously ascribed to mantle metasomatism^{31,33}, subduction of sediments or continental crust^{16,23}, subduction of altered oceanic crust^{27,28} or delamination of subcontinental lithosphere³⁴. Other reservoirs, with characteristics intermediate to the above four may exist as well (such as primitive undepleted mantle^{35,36}).

As discussed above, the San Felix data extend unusually far below the Nd-Sr array (Fig. 2a) and might be interpreted as evidence for a new mantle component, or as evidence that EM I is an end-member to San Felix, rather than to Walvis Ridge. However, the Sr-Pb plot (Fig. 2b) clearly shows that San Felix does not have ²⁰⁶Pb/²⁰⁴Pb ratios suitable for EM I. Rather, it is likely that San Felix is itself a mixture of EM I- and HIMU-type sources. Hart et al.³⁷ have shown that the lowest-Nd samples from Tubuaii, St Helena, New England seamounts, Comores,

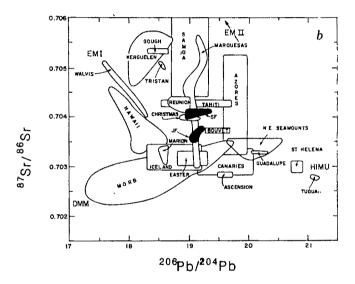

Fig. 2 Nd-Sr (a) and Sr-Pb (b) isotope plots showing San Felix, San Ambrosio and Robinson Crusoe basalt data in comparison with fields for other oceanic island basalts (see refs 2-4). Sample numbers as in Table 1. JF, Juan Fernandez field (individual samples shown in expanded inset in a); SF, San Felix/San Ambrosio data; MORB, mid-ocean-ridge basalts. Locations of four possible endmember mantle components (DMM, HIMU, EM I, EM II) are from ref. 26; see text for discussion. In a, note the linear arrangement of the lowest extensions of the fields for Tubuaii, St Helena, New England seamounts, San Felix and Walvis Ridge. These low-Nd samples also lie on a line in b.

San Felix and Walvis Ridge define a single linear vector in Sr-Nd-Pb space, originating on the mantle plane⁴ near Tubuaii and extending downwards to Walvis. This group of islands shows intra-island isotopic arrays which do not lie along this HIMU-EM I vector, but which extend upward from it toward the mantle plane (though not toward any common end-member on the plane). The implication is that each of these island suites contains a pure (though variable) mixture of HIMU and EM I, and that this mixing preceded the mixing with other components which generated the observed intra-island arrays. In this context, the Juan Fernandez basalts, which lie close to the mantle plane, represent the second mixing end-member of the San Felix-San Ambrosio array. Although this does not settle the question of how the various mantle components came into being, it does suggest that EM I and HIMU are contiguous and related in an evolutionary or kinematic sense, relative to the EM II and DMM components. One scenario would place the EMI and HIMU

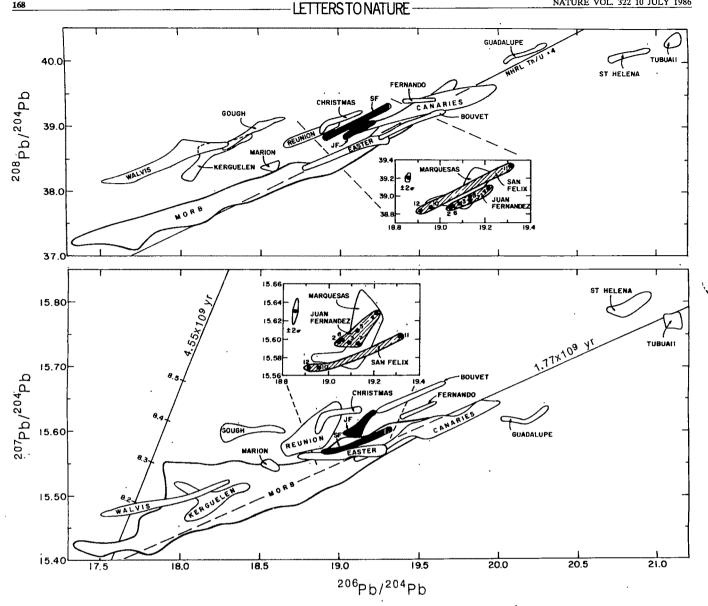

Fig. 3 Pb-Pb-Pb isotope plot showing San Felix, San Ambrosio and Robinson Crusoe data in comparison with fields for other oceanic islands (refs 2-4). JF, Juan Fernandez; SF, San Felix/San Ambrosio; individual data points are shown in expanded insets, with sample numbers as in Table 1; 20 precision estimates are also shown. The Northern Hemisphere reference line (NHRL) of Hart³ is shown for reference, as is a 4.55×10^9 yr geochron (with single-stage μ values indicated at tick-marks). Note that the San Felix/Juan Fernandez data overlap with the data for the Marquesas Islands¹⁸, both in this plot (inset) and in Fig. 2b; however, no overlap exists in Fig. 2a. As in Fig. 2, the low-Nd island samples are also linearly aligned in Pb-Pb-Pb space, (the New England seamount data is not shown on this plot, to avoid graphic confusion). This Tubuaii-Walvis array in fact defines a remarkable 'cross-array' on a 208 Pb/204 Pb - 206 Pb/204 Pb plot, which also includes the fields of a number of 'normal'-Sr-Nd islands.

components in the subcontinental lithosphere; delamination of this lithosphere, followed by mixing with other mantle components, could provide the mixing chronology outlined above³⁷.

We thank H. Banks (Smithsonian Institution) for providing the San Felix samples and K. Burrhus, M. Lezie, A. Gray and P. Guise for excellent technical support. This research was supported by NSF grant EAR 83-08809 (S.R.H.) and by NERC (D.C.G.).

Bacterial scavenging of Mn and Fe in a mid- to far-field hydrothermal particle plume

James P. Cowen*, Gary J. Massoth & Edward T. Baker

Pacific Marine Environmental Laboratory, National Oceanographic and Atmospheric Administration, Seattle, Washington 98115-0070, USA

* Present address: Hawaii Institute of Geophysics, University of Hawaii, 1000 Pope Road, Honolulu, Hawaii 96822, USA

The horizontally advected plumes which originate from buoyant hydrothermal fluid discharges and subsequently mix with entrained ambient sea water have been detected hundreds of kilometres from their vent sources by distinctive chemical hydrothermal tracers such as ³He, Mn and Fe (refs 1-6). Non-conservative plume tracers, such as Mn and Fe, undergo dynamic oxidation-precipitation reactions as the plume is advected away from the vent sources^{1,4,7,8}. Although some of these transformations may be mediated by microbial activity^{9,10}, hydrothermal plumes have largely escaped microbiological examination beyond tens of metres from their vent origins^{11,12}. Microbe-metal interactions in a hydrothermal plume were specifically addressed during our recent expedition (Vent-Plume '85) to the southern Juan de Fuca Ridge (SJFR). The early results, reported here, provide strong evidence of major microbiological influence over Mn scavenging and particulate-Mn distributions.

Microbiological studies of deep-sea hydrothermal vents have been concerned primarily with defining the metabolic processes involved and measuring the magnitude of chemosynthetic productivity (for a review see ref. 13); only a few studies have addressed microbe-metal interactions 11,14. Nearly all of these studies have been confined to the immediate vicinity of the vents. Recently, however, far-field hydrothermal influence has been suggested in bacterial capsule-metal (Mn and Fe) interactions within 50 km of the East Pacific Rise (EPR) at 20° N (ref. 9). Even more recently, elevated microbial biomass has been reported in hydrothermal plumes 100 m above the SJFR vent field10

Fig. 1 Total suspended matter (TSM) isopleths (in µg l⁻¹) for CTD 6 horizontal tow; the horizontal axis represents the perpendicular distance from the valley axis. The sawtooth pattern (dashed) shows the tow-path. The inset shows the relative orientation of CTDs 5 and 6 and the axis of the SJFR (the circle indicates the approximate location of the 4.5-km vertical profile shown in Fig. 3A, B). The arrow marks the plume lateral boundary, and corresponds to similar arrows in Fig. 3C, D. TSM values were derived by the normalized conversion of relative light-scattering values.

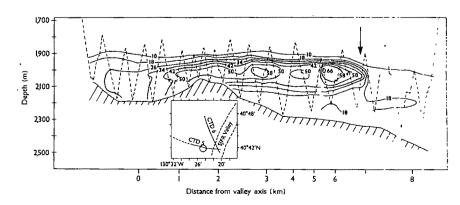

In the present study, the extensive plume (see Fig. 1) emanating from the SJFR axial valley, an area of documented hydrothermal activity¹⁵⁻¹⁸, was tracked in real time with a sensitive electronics package⁶; a rosette of 30-litre Niskin sample bottles was used to sample the plume selectively. Sea water was collected within the plume vertical maximum at distances of 0.9-8.2 km west of the SJFR axial valley, as well as from a vertical cast taken 4.5 km west of the valley (Fig. 1). Samples were analysed for numbers of metal-depositing and total bacteria (Fig. 2A, B; refs 9, 19) and total particulate Fe and Mn (ref. 20); individual particles were also analysed by transmission electron microscopy-energy dispersive X-ray spectrometry (TEM-EDS⁹). The TEM-EDS analyses show that most of the total suspended particulate Fe is present as amorphous hydrous Fe-oxide precipitates (Fig. 2C, D, 3); thus, estimates of relative background Fe-precipitate abundance were made from TEM sections.

Measurements of total suspended matter (TSM) concentrations indicate the depth of the well-defined plume maximum (2,050-2,150 m) at 4.5 km from the nearest hydrothermal source (Figs 1, 3A). Temperature (not shown), dissolved Mn, and particulate Fe anomalies verified the hydrothermal origin of the plume (Fig. 3A). Maxima in the numbers of total bacteria (Fig. 3A) and in two independent biochemical indicators of biomass (ATP and lipopolysaccharides; C. Winn and J.P.C., unpublished data) clearly coincide with the plume depths. The vertical profile of bacterial capsule numbers is less consistent than, but similar to, the corresponding particulate Mn profile: both show generally elevated values at plume depths, increasing towards the bottom (Fig. 3B). Capsules are distinguished by the tremendous surface areas of the extracellular polymer matrices and by the heavy-metal deposits associated with them (Figs 2A, 3A; refs 9, 21).

A horizontal profile through the off-axis plume maximum showed consistently high particle and Fe-precipitate concentrations up to 6.9 km away from the axial valley, beyond which they decline rather sharply (Fig. 3C). Capsule numbers remain high out to a distance of 7.5 km, with a possible gradual decline moving off-axis. Capsule numbers in the first 7.5 km correspond to the maximum values of the vertical profile taken at 4.5 km from the axis (Fig. 3B).

X-ray microanalysis of individual particles revealed large deposits of Mn and Fe associated with the bacterial capsules (Fig. 4A). No other type of plume particle examined so far shows TEM-EDS-detectable (>1,000 p.p.m.) Mn (Fig. 4A). Microanalysis of the common Fe precipitates showed that large concentrations of Mn are not incorporated during the spontaneous chemical precipitation of iron. Furthermore, capsule Mn deposits increase with distance from vents, whereas Fe deposits decrease (Fig. 4A). Such trends are consistent with the total particulate Fe and Mn data (Fig. 3C). These results, together with the high concentration of capsules in the plume. indicate that the bacterial capsules effectively scavenge hydrothermal Mn and thereby influence the partitioning of Mn in the plume.

Radiotracer experiments (Fig. 4B) and elevated microbial

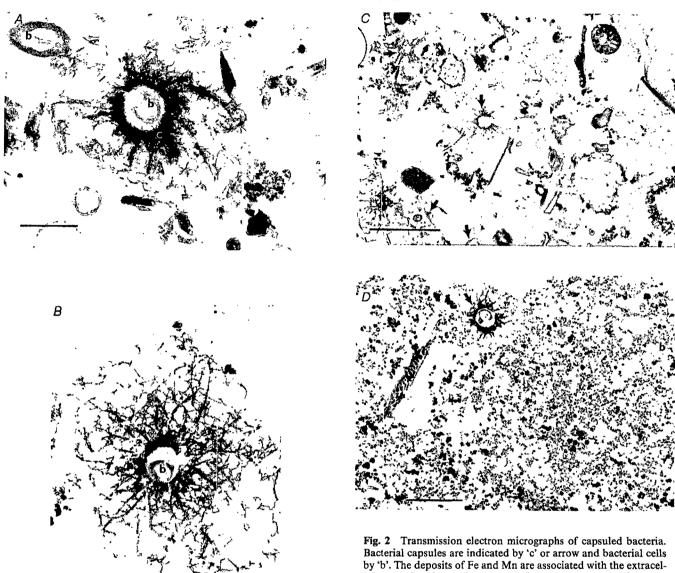

Fig. 2 Transmission electron micrographs of capsuled bacteria. Bacterial capsules are indicated by 'c' or arrow and bacterial cells by 'b'. The deposits of Fe and Mn are associated with the extracellular matrix of organic polymers (capsule or glycocalx). A, B: Scale bars, 1 μm. Lower-magnification micrographs (C, scale bar, 4 μm; D, scale bar, 2 μm) reveal the low (C) or high (D) relative abundance of amorphous Fe precipitate. Bacterial capsules are present in both C and D.

biomass at plume depths suggest that microbial metabolic activity enhances Mn scavenging. Ehrlich¹⁴ has found that some vent microbial mat bacteria exhibit Mn²⁺ oxidizing activity which is associated with cell envelopes and is peculiar to bacteria from vent environments. We do not know whether such activity extends to the capsules discussed here. Alternatively, the observed metal deposition may be non-enzymatic or proceed from some form of metabolic involvement to a predominantly inorganic process.

On the other hand, capsules probably do not have a major role in Fe scavenging or particulate Fe distributions within the plume extending from the axial valley to at least 7 km off-axis. The dominant presence of the amorphous hydrous Fe-oxide precipitates overwhelms the capsule Fe contributions in this portion of the plume. The absence of significant metabolically enhanced ⁵⁹Fe uptake (Fig. 4B) reflects this. Unfortunately, the radiotracer experiments cannot be extended to elucidate the specific mechanism of Fe deposition onto the bacterial capsules. Nevertheless, we postulate that the structural and chemical nature of the capsules themselves may be responsible for the

deposition^{9,22}. The additional involvement of continuously synthesized or recycled enzymes, chelators or other Fe-binding factors may be unnecessary. The occurrence in sediments of a high percentage of empty capsules with elevated Fe and Mn deposits relative to suspended capsules adds indirect evidence in support of passive or surface-enhanced metal deposition⁹.

The origin of bacteria, and especially capsuled bacteria, in hydrothermal plumes is not clear. Greatly elevated biomass has been found in the emitted vent fluids at the Galapagos vent¹². However, Lupton et al.²³, using hydrographic data to characterize the origin of the hydrothermal plume which resides ~200 m above an active hydrothermal field on the Endeavor segment of the JFR^{24,25}, estimated that the plume layer was composed of at least 70% entrained water which had been transported from deeper in the water column. Capsuled bacteria appear to be enriched in near-bottom waters and surface sediments⁹. Furthermore, Fe- and Mn-encapsuled bacteria are common in microbial mats surrounding hydrothermal vents¹¹. It is conceivable, therefore, that the high numbers of capsuled bacteria found in the mid- to far-field plume of the SJFR originated, in part, from

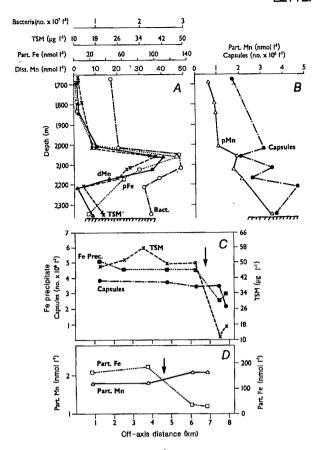

Fig. 3 A, B, Data from a vertical profile taken 4.5 km west of active hydrothermal vent fields, SJFR (40° 42.4' N, 130° 26.1' W), including: A, bacteria numbers, total suspended matter, particulate Fe and dissolved Mn; and B, capsule numbers and particulate Mn. C, Data from the plume maximum along tow-path CTD 6 include capsule numbers, Fe-precipitate relative abundance and particle concentration (TSM). Particulate Fe and Mn from tow-path CTD 5 are given in D. Arrows in C and D indicate the off-axis distance at which the respective tows intersect the plume lateral boundary, as indicated by the arrow in Fig. 1 in the case of CTD 6. Open and closed circles, bacteria and capsule numbers, respectively; open and closed triangles, particulate and dissolved Mn; open and closed squares, total particulate Fe and amorphous Fe precipitate; crosses, TSM concentrations. Bacterial numbers were obtained by filtering 60-100-ml subsamples through black Nucleopore filters (0.2 µm, 13 mm) and using epifluorescent (DAPI) direct counting methods; standard errors for 20 counting fields were 3-6%. Ratios of capsuled bacteria to total bacteria were determined by TEM. Bacteria numbers (DAPI) and capsule/bacteria ratios were determined from the same sample collection bottle for each data point. Capsule numbers were calculated by multiplying bacteria numbers by the ratio of capsules to total bacteria9; TSM concentrations were derived from light-scattering values (attenuation); and relative Fe precipitate abundance was estimated from TEM samples.

the entrainment of near-bottom waters in the vicinity of the - vents. Subsequently, deposition of Mn onto the entrained capsules could proceed within the dissolved-metal-rich plume waters. The latter model would also help to explain the overall vertical profiles for capsules, but not for uncapsuled bacteria. The origin of the latter could be the original emitted vent waters¹² or in situ activity.

Our data provide strong evidence of major microbiological contributions to the scavenging of Mn and particulate Mn distributions throughout off-axis hydrothermal particle plumes. The microbes provide exceptionally large and chemically suitable surface areas (the capsule) for metal deposition. There is also

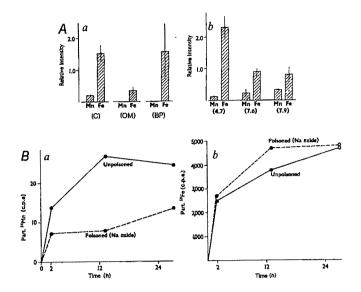

Fig. 4 A, Analysis of individual particles from hydrothermal plume maxima by micro-elemental analysis (TEM-EDS spectrometry); samples used were left completely unstained and analysed with a LINK EDS interfaced with a JOEL 100C STEM. a, Average relative Mn and Fe peak intensities for capsules (C), other minerals (OM) and background Fe precipitate (BP); b, capsule metal deposits at three distances (4.7, 7.6 and 7.9 km) west of the SJFR axial valley; error bars show ±1 s.e. B, Large-volume (6.5 litre) 54Mn and 59Fe uptake experiments using water from the hydrothermal particle plume maximum at 4 km west of the SJFR. Genetic selection for reproductive photoresponsiveness in deer mice

Claude Desjardins, F. H. Bronson & James L. Blank

Institute of Reproductive Biology, Department of Zoology, University of Texas, Austin, Texas 78712, USA

Seasonal breeding is common in mammals, particularly in habitats outside the tropics. Climate and availability of food are the ultimate factors that usually dictate the optimal time of year for a mammal to breed; however, day length (photoperiod) often serves as the proximal cue to signal the onset or cessation of seasonal reproduction¹. Some individuals in some populations of deer mice are reproductively responsive to photoperiod, while other individuals in the same population are not. As shown here, selection can dramatically alter the frequency of photoresponsiveness in a laboratory population in only two generations. To our knowledge this is the first demonstration of selection for reproductive photoresponsiveness in any mammal. By implication, some wild populations of deer mice must use multiple, genetic-based reproductive strategies, and the degree to which each such strategy is exhibited must be subject to rapid change in response to both seasonally and momentarily changing climatic and dietary conditions.

In the northern United States and southern Canada, members of the rodent genus *Peromyscus* usually exhibit a well-defined breeding season. Reproduction is largely limited to the spring and summer when food is plentiful, the climate benign and photoperiod long^{2,3}. Several northern populations of *Peromyscus* have been tested in the laboratory for reproductive responsiveness to photoperiod. Using similar techniques it has been found that reproduction is inhibited by short (winter) day lengths in most but not all of the individuals in these populations^{4–8}. This variation could be attributable to experiential factors encountered either prenatally or postnatally^{9–11}, or it could have a genetic basis. We explored this question by determining the degree to which reproductive photoresponsiveness could be manipulated by artificial selection.

Our test animals were derived from the third generation of a breeding colony of deer mice (*Peromyscus maniculatus nebrascensis*) originally collected near Rapid City, South Dakota (44° N, 103°W). The heterogeneity of this colony's response to photoperiod has been established previously: all individuals mature and breed on long day lengths (light:dark cycle of 16 h:8 h) but only some individuals reach sexual maturity and breed on short day lengths (light:dark = 8:16)⁴.

To begin our selection experiment, 40 pairs were mated on long day lengths, then the females were exposed to short day lengths early in pregnancy. The offspring of these females were defined as the parental generation, and they were weaned at 21-23 days old, maintained one per cage, and the sexes segregated in different animal rooms. The animals were maintained on short day lengths until 8 weeks of age, when their reproductive maturity was assessed. Females were laparotomized, their uteri were recorded as either infantile or partially or fully developed, and their ovaries were examined for corpora lutea as evidence of pubertal ovulation. Testes of males were measured externally using calipers. In each case only completely infantile or fully mature individuals were retained as breeding stock for the next generation.

After 10 weeks on long day lengths to allow sexual maturation of the animals that had been 'suppressed' by short day lengths, two genetic lines were initiated. A reproductively photoresponsive line was begun by mating animals that had remained infantile when reared on short day lengths, and a non-photoresponsive line was begun by mating animals that had matured despite being raised on short photoperiods. Using similar procedures

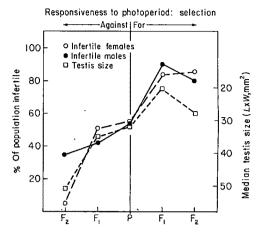

Fig. 1 Change in the frequency of reproductive photoresponsiveness in a laboratory population of deer mice after two generations of selection for and against this trait. The parental generation (P) consisted of 194 individuals of both sexes; 71 of these animals were discarded when they showed intermediate levels of reproductive development at 8 weeks old. Our non-photoresponsive line was begun with 24 pairs, which produced 68 offspring, of which 16 pairs were selected to produce the 43 individuals in the F₂ generation. Our photoresponsive line also was begun with 24 pairs, which produced 83 offspring, of which 16 pairs were selected to produce the 47 individuals in the F₂ generation. L, Length; W, weight.

the resulting two F_1 generations were again directionally selected to produce two F_2 generations.

Figure 1 shows that exposure to a short photoperiod inhibited the reproductive development of about half of the parental generation, while remaining animals were unresponsive to this cue. After two generations of selection only 5% of the females in the non-photoresponsive line had infantile ovaries and uteri when examined at 8 weeks old, as opposed to 86% in the responsive line $(P < 0.001, \chi^2)$. Comparable figures for males with infantile testes were 35% and 80% for the nonresponsive and responsive lines, respectively $(P < 0.01, \chi^2)$. Median testis size at 8 weeks of age also was changed markedly by selection (P < 0.001, median test).

The divergence seen in Fig. 1 confirms a genetic basis for at least some of the variation in reproductive photoresponsiveness that has been observed in deer mice. Indeed, the rapidity with which our two experimental lines diverged suggests that this trait has a high heritability. Two facts argue against the possibility that selection for rate of reproductive development itself was a factor in our experiment 12. First, our assessments of reproductive maturity were made at 8 weeks of age, which is well after the normal onset of fertility in this species. Second, during our selection experiment we always eliminated all animals showing an intermediate level of reproductive development.

Northern populations of deer mice are routinely and predictably exposed to severe winters in their natural habitats. In theory, a rigid use of photoperiod to limit breeding to the spring and summer months would seem to offer a great advantage in this region. Strict reliance on photoperiod would avoid wasted reproductive effort during the normally harsh winters; also, it would allow a long period of metabolic preparation for a short and intense breeding season. Further, it would enforce the many behavioural and physiological adjustments necessary for survival during harsh winters (for example, food hoarding, moulting, metabolic change¹³⁻¹⁵). Nevertheless, occasional winter breeding has been recorded at surprisingly high latitudes in deer mice¹⁶⁻¹⁸; this seems to occur either during climatically benign winters, or when some individuals are able to locate energetically favourable microenvironments characterized by an abundant food supply. Obviously, such breeding is done by animals that are unresponsive to short photoperiods.

Against this background then, our results suggest that selection for and against reproductive photoresponsiveness must be an exceptionally dynamic process in Peromyscus. Many northern populations of this genus must be composed of two or more phenotypes that vary genetically in their reproductive responsiveness to photoperiod. Animals that are not responsive to short day lengths could breed in the summer, but they would probably suffer high mortality during a typically harsh winter. On the other hand, should such individuals encounter a mild winter, or should they find a suitable microclimate during a harsh winter, they could reproduce and thereby add their genes to the population at a time when its size is at its lowest point. Thus, one can visualize a continual balancing of these selective forces, with the result being a highly labile trait whose frequency in a population could shift markedly over short periods of time.

The potential for dynamically changing, multiple reproductive strategies within Peromyscus populations has been suggested previously¹⁹. The present demonstration of successful selection for reproductive photoresponsiveness—the first in any mammal-reinforces this possibility. Indeed, the use of multiple reproductive strategies within a population is probably not limited to mid-latitudinal populations of Peromyscus, and may not even be limited to photoperiodic regulation^{8,20,21}. Most species of small rodents have short life expectancies, and most environments are relatively unpredictable for animals whose lifespans are measured in weeks or months. Reproductive success under such conditions must require great flexibility in reproductive strategies. The prevailing concept that the reproductive traits of a population have been exclusively tailored to the average, long-term physical and dietary characteristics of its habitat probably is not applicable to many populations of small mammals.

We thank Donald W. Caroll and Janet Darrow for their assistance with this research, and Janet Young for preparing the illustrations. This research was supported in part by grant AG00958 from the National Institute of Aging, grant HD-13470 from the National Institute of Child Health and Human Development, and NSF grant PCM 8208389.

Trypanosomes of the species Trypanosoma brucei reproduce primarily by binary fission, but the frequency of enzyme electrophoretic variants in natural populations of T. brucei has provided indirect evidence for the existence of a sexual cycle¹⁻³. These studies, coupled with studies of restriction fragment length polymorphisms of genes encoding glycolytic enzymes⁴, have also provided evidence for T. brucei being diploid. Here we report direct evidence of gene exchange between two different clones of trypanosomes after mixed infection and full cyclical development in the tsetse fly vector.

Two cloned trypanosome populations (247-L and 386AA) were fed, either separately or as an equal mixture, through a membrane to different groups of tsetse flies (see Fig. 1). Flies showing the presence of metacyclic-stage trypanosomes (indicating completion of full cyclical development) were allowed to feed on mice and the resulting bloodstream infections (386AAA, 723C and 247LA) passaged to produce trypanosome lysates. In addition, a single clone (723CA) was isolated⁵ and then re-transmitted through a tsetse fly to yield the trypanosome populations 723CAB and 723CAE (Fig. 1). From an independent mixed transmission of the two parental clones, two further

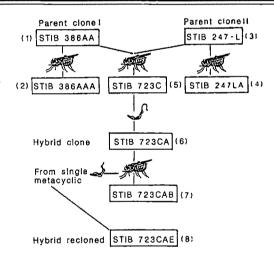

Fig. 1 Pedigree of mixed-infection experiment. Clone STIB 247-L is a derivative of the primary isolate STIB 247, obtained from Coke's hartebeest in the Serengeti National Park, Tanzania, in (ref. 8). Clone STIB 386AA is derived from TH 114/78 E (020), isolated in 1978 from a patient on the Ivory Coast9. Glossina morsitans centralis (ILRAD colony) were fed through a membrane on bloodstream trypanosomes from each clone mixed in equal proportions (total of 6×10⁷ trypanosomes per ml). Two further groups of G.m. centralis were fed at the same time on each of the two clones separately (6×10^7) trypanosomes 1). The flies were maintained at 28 °C in 75% relative humidity; they were membrane-fed three times a week on rehydrated pig blood¹⁰. All clones were established using the hanging-drop method of Van Meirvenne et al.⁵.

clones (723VI-L and 723VI-M) were derived directly from the metacyclic stage.

The two cloned stocks used in mixed tsetse fly transmission were screened for electrophoretic variation using starch gel electrophoresis or isoelectric focusing (IEF) and were found to differ in five enzymes—phosphoglucomutase (PGM), isocitrate dehydrogenase (ICD), alkaline phosphatase (AP), malic enzyme A (MEA) and malic enzyme B (MEB) (Fig. 2). Four of the enzymes show single bands of activity which differ in electrophoretic mobility between the two clones, while in the fifth enzyme (MEB), one clone shows a three-banded pattern and the other a single-banded pattern of identical mobility to the fastest band of the first clone.

The parental clones (numbered 1 and 3 in Fig. 1), the clones derived from separate cyclical transmission of these clones (2) and 4) and the clones derived from mixed transmission (6, 8 and 723VI-L) were screened by starch gel electrophoresis or IEF for the enzymes AP, ICD, PGM, MEA and MEB; Fig. 2 shows the results. The enzyme phenotypes of the parental clones remained unchanged after transmission through the tsetse fly. whereas the enzyme phenotypes of the stocks derived from the mixed transmission were found to differ from those of either parental clone and appeared to be heterozygous for the variant alleles for which the parental clones were homozygous (AP, ICD, PGM and MEA). These results are not due to the presence of mixtures of the parental clones in the tsetse-transmitted progeny, as populations 6, 7 and 8 are clones or directly derived from clones. Thus, mixing of the two parental stocks, followed by transmission through the tsetse fly, results in populations with non-parental phenotypes which are hybrid or heterozygous for parental homozygous markers. Identical results were obtained on analysis of clone 723VI-L, which is derived from a metacyclic form of an independent mixed transmission. These results clearly demonstrate that new, non-parental phenotypes (and therefore genotypes) can be generated by transmission of mixed trypanosome clones through tsetse flies. In addition, the transmission of either parental clone individually or the cloned hybrid progeny (clone 6) results in no alteration of the enzyme markers, implying that individual cloned stocks are stable in terms of phenotype and genotype after tsetse fly transmission.

Probes detecting restriction fragment length polymorphisms (RFLPs) in the genomic DNAs of the parental trypanosome clones were prepared as described in Fig. 3 legend. Southern hybridization of these probes with digests of DNA prepared from hypanosome clones 1, 2, 3, 4, 7, 9 and 10 revealed simple patterns of inheritance. Two probes, pDB9 (Fig. 3a,d) and pBG11 (not shown), revealed that the parental clones are homozygous and differ at the sites detected; the hybrid clones are heterozygous. Probe pBE2 (Fig. 3c) detected a family of fragments generated by EcoRI. The hybrid clones inherited all but one of these parental fragments. The results in Fig. 3c are compatible with most of the sites detected in the parental clones being homozygous, and those in the hybrid clones being heterozygous. Examples of markers that are heterozygous in one parent and homozygous in the other have been found using single-copy probes. Among these probes, pBE9 (Fig. 3b,e) detected an instance of the hybrids behaving as homozygotes and not inheriting all the fragments detected in the parents. This result, together with the non-inheritance of the arrowed band in Fig. 3c, demonstrates that the hybrids differ from both parents. The hybrid genotypes have also been detected in trypanosomes isolated from the field, suggesting that they occur naturally.

The DNAs of parental and hybrid trypanosome populations were analysed with DNA probes for variant surface antigen genes (see Fig. 4). The probes are specific for the genes encoding the AnTat 1.1 and 1.8 antigens which have been characterized previously in *T. brucei* stock EATRO 1125 (ref. 6). Both probes, in conjunction with a variety of restriction enzymes (not all shown here), provide restriction patterns that differ between the two parental clones; this result is in keeping with the considerable restriction polymorphism of antigen-specific sequences observed in *T. brucei*. As shown in Fig. 4, the mixed cyclical transmissions gave rise to 'hybrids' with different patterns of reassortment. The pattern revealed in the hybrids by the AnTat 1.1 probe (Fig. 4a) included all the fragments from both parents. The AnTat 1.8 probe (Fig. 4b) revealed a pattern combining all

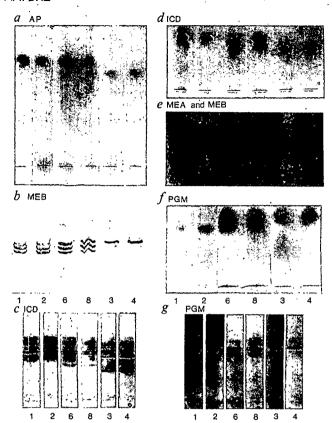

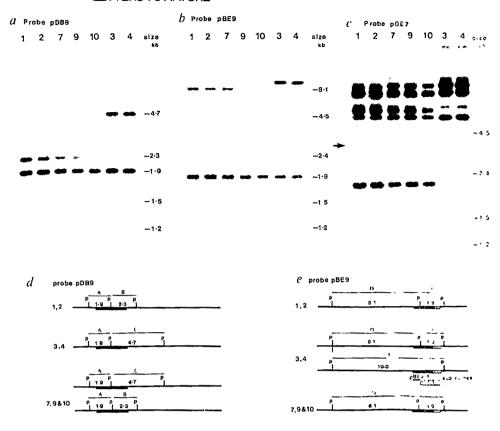

Fig. 2 Starch gel electrophoresis (a, d, e, f) and isoelectric focusing (b, c, g) of extracts of purified trypanosome clones 1-4, 6 and 8. After completion of electrophoresis or focusing, the gels were stained for alkaline phosphatase (AP, a), phosphoglucomutase (PGM, f and g), malic enzyme A (MEA and MEB, e), isocitrate dehydrogenase (ICD, c and d) and malic enzyme B (MEB, b). The methods and buffer systems used for these separations have been described previously 3,11,12 . The derivation and relationships of the trypanosome populations are shown in Fig. 1.

the fragments from parent 1 with only some fragments characteristic of parent 2. Clearly, some AnTat 1.8 gene family members (indicated by arrows in Fig. 4) were not transmitted to the progeny. The reassorted patterns were conserved through successive clonings and retransmission.

The results presented here directly demonstrate, for the first time, that genetic exchange occurs in T. brucei. Clearly, by mixing two trypanosome clones and transmitting the mixture through tsetse flies, trypanosome populations of non-parental phenotype and genotype are produced. With all the markers used, except for the gene probes AnTat 1.8 and pBE9, the progeny derived from mixed transmission of the two trypanosome clones were hybrid or heterozygous for parental markers. The restriction patterns of all these markers would fit a mendelian model of meiosis of the parental strains followed by fusion of a haploid stage, but other interpretations could be proposed to explain the results. The demonstration of genetic exchange in T. brucei potentially opens up a new field of trypanosome researchgenetic analysis—which should allow the genome to be manipulated. However, considerable further analysis is required to define the basic properties of this new genetic system and to determine whether meiosis occurs; such analysis is currently being undertaken.

Fig. 3 Detection of RFLPs in parental and hybrid trypanosomes. a-c, The results of Southern hybridizations with probes detecting RFLPs in enzyme digests of parental (1-4) and hybrid (7, 9, 10) DNAs. In d and c, homozygous chromosome fragments are represented by a single line; heterozygous chromosome fragments are shown as double lines. Fragments detected by the probes in Southern blots of PstIdigested trypanosome DNAs are lettered A-F. Heavy bars indicate the cloned fragments used as probes. DNA preparations are numbered as in Figs 1, 2 and 4. a Is interpreted in d as indicating the presence of homozygous marker fragments in the parental clones, and heterozygous markers in the hybrids; pDB9 detects two fragments in the parental stocks 1-4. Fragment A is detected in trypanosome clones 1-4, fragment B in clones 1 and 2 and C in 3 and 4. The hybrids (7, 9 and 10) are all heterozygous for fragments B and C. In b the homozygous marker fragments in clones 7, 9 and 10 appear to have segregated from homozygous × heterozygous parental combinations (e). Probe pBE9 detects two fragments, D and E, in 1, 2, 7, 9 and 10 and an additional fragment, F, in the heterozygous parental stocks 3 and 4. Fragment F is detected because of

polymorphism at the Pst1 site in the cloned sequence. Pst1 subclones (pBE9-1 and pBE9-2) both hybridize to fragment F. The inheritance of a number of fragments detected with probe pBE2 (c). One fragment (arrowed in 1 and 2) is not inherited by hybrid clones 7, 9 and 10. Methods. Bloodstream-form trypanosomes were transformed to procyclic trypanosomes in Dulbecco's modified Eagle's medium (DMI M) containing 10% fetal bovine serum at 28 °C over irradiated fibroblast feeder layers (2,000 rad; Flow 2002 cells). Procyclic organisms were grown to late log phase in SDM 79 medium¹³, and DNA prepared using standard procedures^{14,15}. Genomic clones were prepared from a reference strain of T. brucei (8/18)¹³. Genomic DNA was digested with EcoRI and 2.5-5.1-kilobase fragments purified by electroclution from an agarose gel¹⁵. These fragments were ligated with EcoRI-digested pJSC73 (ref. 16) and used to transform Escherichia coli HB101 Colonies containing plasmids with inserts were detected by the colour selection method 16 and plasmids prepared by a rapid isolation procedure. After electrophoresis in 0.8% agarose, the plasmids were transferred to nitrocellulose filters and hybridized with nick-translated total genomic DNA from the reference strain $(1-2\times10^8 \text{ c.p.m.})$ per μg DNA)^{18,19}. Filters were washed three times for 30 min each in $2\times SSC$ plus 0.1°. SDS at 65 °C, and exposed to Fuji X-ray film at -70 °C for up to 5 days, with an intensifying screen. Recombinant plasmids yielding the weakest signals in our conditions identified single- or low-copy number sequences. Southern hybridization 8 of these probes to trypanosome DNAs from parental and hybrid clones digested with different restriction enzymes was used to detect RFLPs; filters were washed under conditions of high stringency (0.1 × SSC, 0.1% SDS at 65 °C) and autoradiographed.

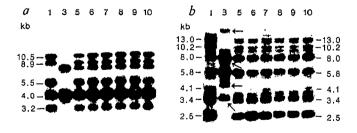

Fig. 4 Detection of restriction fragments specific for the genes encoding the antigens AnTat 1.1 (a) and AnTat 1.8 (b) in parental and hybrid trypanosomes. The different DNA preparations (1, 3, 5-8) are numbered according to the pedigree shown in Fig. 1. Tracks 9 and 10 contain DNAs from hybrid clones (723VI-L and 723VI-M) obtained in an independent mixed transmission experiment. The antigen-specific fragments of the hybrids (tracks 5-10) appear to be a combination of those of the two parental clones (tracks 1 and 3), except for the arrowed fragments in lane 3, which are not transmitted to the progeny.

Methods. The AnTat 1.8 and 1.1 probes were prepared as described previously6, then nick-translated and hybridized to Southern blots of genomic PstI digests, obtained as described in Fig. 3 legend.

Several observations suggest that retroviral infection is involved in the pathogenesis of the human demvelinating disease multiple sclerosis (MS). First, lymphadenopathy-associated virus/human T-lymphotropic virus type III (LAV/HTLV-III), the agent of acquired immune deficiency syndrome (AIDS), has been shown to be neurotropic in man1. Second, the genetic organization of the lentivirus visna, which causes a chronic demyelinating disease of sheep, closely resembles that of LAV/HTLV-III². Recently, Koprowski and colleagues reported that MS is associated both with raised levels of circulating antibodies to HTLV-I and with the presence of HTLV-I-specific RNA within cell lines derived from the cerebrospinal fluid (CSF)3. Here we report that no HTLV-I-like or LAV/HTLV-III-like sequences can be detected, by in situ hybridization, in central nervous system (CNS) tissues from MS patients, and that no specific HTLV-I-like signal in peripheral blood mononuclear cells or in CSF cell lines is characteristic of MS. Furthermore, enzyme-linked immunosorbent assay (ELISA) analysis of circulating and CSF antibodies for HTLV-I reactivity fails to distinguish between MS and control groups.

Tissue blocks of active white matter lesions from 12 MS patients were selected for the presence of inflammation, macrophage infiltration and active demyelination; in some cases variable gliosis was also present (Fig. 1a). In situ hybridization was performed on serial sections, using a probe complementary to the long terminal repeat, pX, gag, pol and env regions of the HTLV-I genome, a probe complementary to the entire LAV/HTLV-III genome, and a control pBR322 probe. No specific RNA sequence was detected in any section following autoradiographic exposure times of 1 and 2 weeks.

Circulating mononuclear cells from 18 MS patients and 18 control individuals were separated by density gradient centrifugation, mounted on acetylated slides by cytocentrifugation and fixed. Table 1 shows the results of in situ hybridization with the HTLV-I and pBR322 probes. Cells were defined as positive when the number of grains counted was greater than five times background (Fig. 1b). It is noteworthy that both the HTLV-1 and pBR322 probes labelled a small number of cells $(10^{-4}-10^{-5}$ cells counted) in approximately half of both the MS and control samples. The morphology of cells labelled by both probes was heterogeneous and included small cells with scant cytoplasm, presumably lymphocytes, and, prominently, some larger cells with cloven or bi-lobed nuclei (Fig. 1c). Eosinophils, which were occasionally present in some samples, were also labelled by each of the probes; nonspecific labelling of this cell type during in situ hybridization has been noted previously4; no differences were present between the MS and control populations (Table 1).

CSF lines were derived from three individuals with active MS by stimulation with phytohaemagglutinin-P and by expansion with medium supplemented with interleukin-2 (Biotest). No positively labelled cells were detected in any of the three lines following in situ hybridization with the HTLV-I probe (10⁵ cells counted per sample) (Table 1). Analysis of peripheral blood

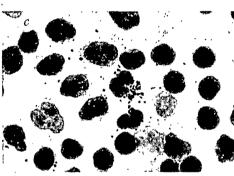

Fig. 1 a, Perivascular and parenchymal inflammation is present at the edge of an active MS plaque (haematoxylin-eosin). b, In situ hybridization of peripheral monuclear cells with the HLTV-I DNA probe. The figure shows a typical small round cell which was labelled by the HTLV-I probe. c, A peripheral blood mononuclear cell with a cloven nucleus is labelled by the HTLV-I probe. Methods. a, For this study, fresh frozen necropsy (n = 11) or biopsy (n=1) brain material was derived from patients with clinically definitive and pathologically confirmed MS. The MS material used is part of a larger collection which has been described previously⁶. Serial sections from each frozen tissue block were mounted on pretreated slides^{4,7}, fixed with ethanol acetic acid (3:1 vol/vol), and hybridized in situ as described elsewhere, including pretreatments with acid, heat and proteinase $K^{4,7}$. DNA probes for HTLV-I, LAV/HTLV-III and pBR322 sequences were labelled by nick translation with 35S to a final specific activity of 2×105 d.p.m. per ng. After washing, slides were dipped in Kodak NTB-2 emulsion, exposed for 11 days, developed and counterstained with a Giemsa stain. b, Cells were prepared by density gradient centrifugation, mounted on microscope slides with a cytocentrifuge and fixed in 0.5% formaldehyde, 0.5% glutaraldehyde, 0.1 M phosphate buffer pH 6.0, 1.6% glucose, 0.002% CaCl₂, 1.0% dimethyl sulphoxide⁸. In situ hybridization was performed as described above for brain

mononuclear cells from each of these patients had shown that several positive cells were detected with both the HTLV-I and pBR322 probes at the time that the CSF lines were established.

Serum antibody reactivity against HTLV-I was measured by ELISA, and no differences were found between a larger group of MS and control patients (Fig. 2). Serum from one MS patient was strongly reactive with HTLV-I, a finding confirmed by

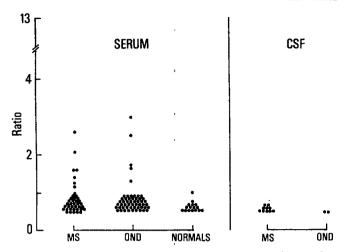

Fig. 2 Distribution of antibodies to HTLV-I in MS patients and controls. Coded serum and CSF samples were tested by the Biotech HTLV-I ELISA test using as antigen semipurified disrupted HTLV-I virions produced by the HUT-102 cell line9. The level of positivity was estimated by the ratio of absorbance between the test serum and the average of duplicate negative sera. OND, other neurologi-

immunoblot analysis. Sera from two other MS patients were weakly reactive by ELISA but negative by immunoblot. Serum from one control, a patient with amyotrophic lateral sclerosis, was weakly reactive against HTLV-I both by ELISA and immunoblot. CSF samples from 10 MS patients were uniformly unreactive to HTLV-I by ELISA (Fig. 2). CSF and brain material was available from one MS patient whose serum was reactive to HTLV-I by ELISA, and in this patient no CSF antibodies or viral RNA in brain tissue was found.

These results fail to confirm a recent report implicating infection with an HTLV-I-like virus in MS³. It is unlikely that this discrepancy is due to a difference in patient selection, as the MS population chosen for our study consisted of patients with both the relapsing-remitting and the chronic progressive forms of the disease and included patients from both Europe and the United States. The present study also represents the first analysis of HTLV sequences in MS brain material and the negative results obtained contrast with the finding that LAV/HTLV-III-specific sequences can be detected by in situ hybridization in the brains of some AIDS patients¹, a finding confirmed in our laboratory Vazeux and M.B., in preparation). The absence of circulating antibodies to HTLV-I in this population is also in striking contrast to the consistent findings of one of us (G.deT.) in patients with tropical spastic paraparesis⁵.

These results do not rule out the possibility that a small percentage of MS patients might be found to have an associated HTLV-I infection. In the present study, the one patient (of 42

Table 1 In situ hybridization of mononuclear cells in multiple sclerosis

		Specific r with H	
Source	Diagnosis	Present	Absent

^{*} Specific hybridization with the HTLV-I probe was defined as those samples in which cells were labelled only with HTLV-I or in which the frequency of cells labelled with this probe was greater than that present with the control pBR322 probe.

tested) showing a strong serological response to HTLV-I was of French origin and not distinguishable on clinical grounds from the other MS patients studied. It also remains possible that an as yet undefined retrovirus is present in MS. In this regard, the extensive antigenic and sequence diversity which exists between different retroviruses makes it likely that other methods will be required to identify the presence of such agents in human disease states.

We thank Dr Masakazu Hatanaka for the generous gift of HTLV-I cloned DNA, Dr S. Wain-Hobson for the gift of LAV/HTLV-III cloned DNA, Drs Byron Waksman and Elisabeth Tournier for helpful discussions and B. MacMillan for technical assistance. The recent report by Koprowski et al.1 that human T-cell lymphotropic retroviruses (HTLVs) may be involved in the development of multiple sclerosis (MS) has aroused much interest². The report was based largely on immunological evidence, using enzymelinked immunosorbent assays (ELISAs) with viral antigens or disrupted virions. We have accordingly sought confirmation by screening sera and cerebrospinal fluid (CSF) samples from MS patients against cell lines infected respectively with adult T-cell leukaemia (ATL) virus (ATLV/HTLV-I) of Japanese cells (MT-1 and MT-2 lines), our own isolate from British black patients with ATL, the MoT cell line which produce HTLV-II, and our own T-cell line containing a local isolate of acquired immune deficiency syndrome (AIDS) virus (C-LAV/HTLV-III). We have failed to find antibodies against these retroviruses in the sera or CSF. Furthermore, neither virus could be isolated from the peripheral white blood cells of two MS patients.

We have used the cell-based immunoperoxidase (IP) method, which we developed and found to be a highly sensitive test³ for antibodies to the AIDS virus and to ATLV/HTLV-I. In both tests, virus-infected cells which produce large quantities of the viral antigen were used. Each sample was tested in duplicate and also included a control (non-infected cells). The results of the IP reaction could be clearly distinguished by the naked eye

[†] Includes 11 individuals with a variety of non-MS neurological diseases and 7 normal controls.

and verified by examination under conventional low-power microscopy. This allows for the elimination of false readings associated with radioactivity of ELISA counters.

Table 1 lists the origin and clinical state of the sera and CSF and shows that we failed to detect antibodies to the oncoviruses (ATLV/HTLV-I, HTLV-II) or to the lentiviruses (LAV/HTLV-III) in any of the 46 sera and 15 CSF from MS patients.

In our preliminary studies we also tried to isolate a retrovirus from the peripheral white blood cells (WBC) of two patients with MS. The WBC were separated on Ficoll before being divided into two parts. One part was co-cultivated with fresh

Table 1 Results of retrovirus tests

		ATLV/ HTLV-I	HTLV-II	LAV/ HTLV-III
UK:	Paired, MS sera	0/15	0/15	0/15
OIL.	MS CSF	0/15	0/15	0/15
	Paired, OND sera	0/20	0/20	0/20
	OND CSF	0/20	0/20	0/20
Sweden: MS sera		0/21	0/21	0/21

MS, multiple sclerosis; CSF, cerebrospinal fluid; OND, other neurological diseases, including suspected but not confirmed MS; ATL, adult

human cord WBC and the other part was cultured with the Karpas T cells³. If ATLV/HTLV-I or HTLV-II were involved in MS, one might expect the cord WBC to become infected and express the viral antigen. In contrast, if an AIDS-like lentivirus was involved, one would have expected cell lysis of both the cord T cells and our T-cell line, or at least development of an antigen that reacted with sera containing antibodies to LAV/HTLV-III or ATLV/HTLV-I.

The two cultures of cord cells, and the two cultures of our T-cell line, which were co-cultivated with the WBC from the MS patients, were tested for the expression of ATLV/HTLV-I and LAV/HTLV-III after 2 and 4 weeks in culture, using the IP method. Neither the cord WBC nor our T-cell line expressed any antigens that reacted with human sera containing antibodies to ATLV or to LAV. Since sera of patients with ATLV contained antibodies which cross-reacted with HTLV-II, one would expect these sera to react with HTLV-II-infected cells if a related virus is involved in MS.

In summary, we failed to detect any antibodies against ATLV/HTLV-I and HTLV-II or LAV/HTLV-III in the sera and CSF samples from MS patients, nor could either of these viruses be isolated from the WBC. The claim to the presence of antibodies which react with the known human retroviruses is based on ELISA tests. We now know that some of the ELISA systems may give a high rate of false-positive results. The report that 37% of Israeli Falashas were ATLV/HTLV-I-positive has turned out to be wrong, probably due to the ELISA method⁴. Similarly, it has been repeatedly reported that some of the ELISA test kits used for AIDS screening give a high rate of false-positives^{5,6}. The results of such ELISA methods might cause premature claims to the involvement of HTLV in MS.

The possible viral aetiology of MS remains enigmatic; should a retrovirus eventually prove to be a pathogenic factor, it is likely to be distinct from the known human retroviruses.

We thank Professor P. Lachmann for providing some of the serum/CSF samples.

KOPROWSKI ET AL. REPLY: We are pleased that other investigators^{1,2} have undertaken the difficult task of searching for the involvement of retroviruses in multiple sclerosis. However, it is difficult for us to compare the results of our study³ with the data presented by Hauser et al. and Karpas et al. The first study used a commercially prepared kit for HTLV-I antibody while the second used visual detection of HTLV-I antibody by immunoperoxidase on infected cells. The drawback of both these assays is that the concentration of the HTLV group-specific (gag) antigen p24 in the kit is unknown and is considerably lower in cells than that used for our antibody determinations by ELISA. Despite this, the results of Hauser et al.1 with MS sera and normal controls are almost identical to the results shown in our Fig. 23. The discrepancy between our results and theirs with other neurological disease (OND) patients may be explained if we knew which OND patients were tested by Hauser et al.1. While Karpas et al.2 may find their immunoperoxidase test sensitive enough to detect antibodies in extremely high-titred AIDS⁴ and in eight leukaemia sera, we expect that this assay would not detect low-titred (HTLV-I cross-reactive) antibody found in MS patients. Because of the fluctuation of the HTLV p24 antibody levels, it does not make sense to search with low-sensitivity assays for antibodies in a single sample of either serum or cerebrospinal fluid of MS patients. 'False-positives' in our ELISA were excluded by specific competitive inhibition assays³.

The inability of Hauser et al.1 to detect retroviral sequences by in situ hybridization may be due to several factors: (1) use of complementary DNA probes rather than the much more sensitive riboprobes^{5,6}; (2) the stringency conditions under which the test was run (not mentioned by Hauser et al.1 but crucial in our assay); (3) restriction of sensitivity of the test by nonspecific hybridization with pBR322 plasmid alone. Hauser et al. provide neither positive controls showing the limitation of the sensitivity of the test nor controls confirming the presence of hybridizable RNA in the lymphocytes.

In the light of the considerable time and effort invested in the isolation of the human retroviruses I, II and III, it is not surprising that Karpas et al.2 failed to isolate the 'MS virus' from two randomly chosen MS samples in 4 weeks. We also emphasize points repeatedly made in our report that detectable antibodies are: present in low titre; cross-reactive, that is, not reactive specifically against the test HTLV; and, most importantly, present only sporadically in cerebrospinal fluid and sera during the course of disease. Karpas et al.² made a point that if HTLV is involved in MS, it is "distinct from the known human retroviruses". We agree and that was precisely our conclusion.

A functional T3 molecule associated with a novel heterodimer on the surface of immature human thymocytes

Ilan Bank*, Ronald A. DePinho†, Michael B. Brenner‡, Judy Cassimeris*, Frederick W. Alt† & Leonard Chess*

The known T-cell receptors (TCRs) involved in the recognition of antigen and major histocompatibility complex (MHC) molecules are glycoproteins comprised of polymorphic disulphide-linked α and β -chains 1-5. The genes encoding these chains are homologous to immunoglobulin genes and consist of V (variable), J(joining) and C (constant) regions that rearrange during development⁶⁻¹³ TCRs are expressed relatively late in thymocyte development and only in association with an invariant molecular complex of proteins termed T3 (refs 3, 14). Immature thymocytes do not express the TCR-T3 complex but do express messenger RNA encoding a third rearranging T-cell receptor-like gene, termed T γ (refs 13, 15–20). Here we report a clone of normal immature T4T8 human thymocytes, designated CII, which does not express mature mRNA for $T\alpha$ or $T\beta$ genes, but does express high levels of $T\gamma$ mRNA. This clone also expresses high levels of surface T3, and antibodies to T3 induce immunologically relevant functions in CII cells. Immunoprecipitation of CII surface-labelled proteins with anti-T3 co-precipitates a T3 molecular complex together with two additional and novel peptides of relative molecular mass (M,) 44,000 (44K) and 62,000 (62K).

To isolate immature T4⁻T8⁻ cells, human thymocytes were treated with anti-T4 and anti-T8 antibodies, and T4⁺ and T8⁺ cells were removed by rosetting with anti-mouse immunoglobulin-coupled red cells^{15,20-22}. The original thymocyte population contains cells expressing the T11, T3, T6, T4 and T8 antigens (Fig. 1a). In contrast, the non-rosetting population lacks T4- and T8-bearing cells but expresses the T11 and T6 surface antigens (Fig. 1b)^{20,23}. The T4⁻T8⁻ cells constituted 3.5% of the total thymocyte population and the number of these cells expressing T3 varied between 0 and 5%. To generate continuous cell lines, T4T8 cells were cultured with interleukin-2 (IL-2) and feeder cells. Over a short culture period (4 days), T4⁻T8⁻ cells lost expression of T6 and 80-90% of the cells expressed high levels of T3 (Fig. 1c). Cloning of these cells yielded several T3⁺T4⁻T8⁻ cell lines, one of which, CII, was studied in further detail. CII remains an IL-2- and feeder celldependent cell line which continues to be T3⁺, T4⁻ and T8⁻ (Fig. 1d). We confirmed the T4⁻T8⁻ phenotype of CII by Northern blot analysis. Neither the 3.0-kilobase (kb) T4 mRNA nor the 2.4-kb T8 mRNA was expressed in CII (refs 24, 25 and data not shown).

We next assessed whether the T3 molecule on CII cells was functional. Mature T cells can be activated by anti-T3 antibody in the presence of the phorbol ester 12-o-tetradecanoyl phorbol acetate (TPA) to secrete IL-2^{26,27}. When CII cells were stimulated with TPA in the presence of anti-T3 antibody (OKT3), significant amounts of IL-2 were produced (Fig. 2a). In contrast, TPA alone or anti-T11 (OKT11A) and TPA resulted in only minimal IL-2 release. In addition, CII, like mature T cells, could be activated to proliferate by OKT3 in the presence of monocytes²⁸. A monocyte-enriched (E⁻) population was irradiated and added to CII cells in the presence or absence of anti-T3 or control anti-T11 antibody. Anti-T3 but not anti-T11 induced a significant proliferative response which required the presence of E⁻ cells (Fig. 2b). Neither CII cells nor irradiated E⁻ cells

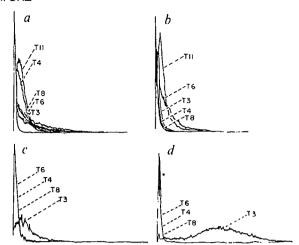

Fig. 1 Cytofluorographic analyses of fresh thymocytes (a), freshly selected T4 T8 thymocytes (b), cultured T4 T8 cells (c) and the clone CII (d) Methods. Thymus tissue was obtained from children 2-11 years old undergoing cardiac surgery, and single-cell suspensions were prepared. To obtain T4-T8- cells and the reciprocal T4+T8+ cells, unfractionated thymocytes were treated for 30 min at room temperature with a combination of OKT4 (1/1,000 of ascites) and OKT8 (1/2,000 of ascites), and rosetted with ox red blood cells coupled to rabbit anti-mouse IgG at a final haematocrit of 2.5% ^{34,35}. Rosetting (T4⁺ and T8⁺) cells were separated from non-rosetting (T4T8-) cells by Ficoll-Hypaque density centrifugation. The rosetting red cells were lysed with Tris-buffered ammonium chloride to obtain a pure $T4^+T8^+$ population²². $T4^-T8^-$ cells were cultured at 1×10^6 cells ml⁻¹ in the presence of 0.5×10^6 cells ml⁻¹ of irradiated (7,000 rad) B-lymphoblastoid cells, in a final volume of 2 ml in 12-well tissue culture plates (Costar). Recombinant IL-2 (100 U ml⁻¹; Hoffman-La Roche), and 1% phytohaemagglutinin (Gibco) were added. The final medium for all cultures was Iscove's modified Dulbecco's medium (Gibco) supplemented with 1% penicillin-streptomycin (Gibco) and 10% fetal calf serum (Hyclone), and cultures were grown in a humidified atmosphere with 5% CO, at 37 °C After 4 weeks of bulk culture, cells were cloned at limiting dilutions in 96-well round-bottom plates with lymphoblastoid feeders and expanded under conditions similar to those used in the initial bulk culture. For cytofluorographic analysis, 105 cells were incubated at room temperature with a 1/2,000 dilution of the appropriate antibodies (OKT11, OKT6, OKT4, OKT8 or OKT3) for 30 min. The cells were then washed and incubated for an additional 30 min at 4 °C with fluorescein-conjugated goat anti-mouse immunoglobulin (G/M FITC) (Cappel Laboratories) and washed. The cells were analysed on a Model 30-H Cytofluorograf (Ortho Instruments). The results shown represent analysis of 104 cells for each population as indicated

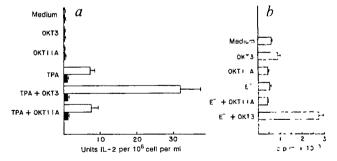

Fig. 2 Activation of CII cells by anti-T3 antibodies to secrete 1L-2 and proliferate. a, CII cells (open bars) or B-lymphoblastoid cells (closed bars) were washed and placed in 96-well microtitre plates in fresh medium at a concentration of 0.5 × 10⁶ cells ml⁻¹ in a final volume of 200 μl. TPA (Sigma) was added to the cultures at 5 ng ml⁻¹. OKT3 or OKT11A was added at a final concentration of 1/500 of ascites fluid. After 24 h, the supernatants were collected and added to the murine IL-2-dependent CTLL cell line²⁷. After overnight incubation at 37 °C in a humidified atmosphere with 5°s CO₂, the proliferation of CTLL was assessed by ³H-thymidine incorporation over an additional 6 h. A standard reference curve was obtained for each experiment, and the IL-2 units calculated as described previously³⁶. The results shown are expressed as units of IL-2 produced per 10⁶ cells ml ¹, and represent the mean±1 s.d. of triplicate wells. b, CII cells were washed and placed at 1×10⁶ cells in a volume of 200 μl in 96-well flat-bottom plates. E⁻ cells, obtained from normal donor peripheral blood mononuclear cells, were irradiated (2,000 rad) and added at 0.5×10⁶ cells ml⁻¹ (ref. 37) OKT3 and OKT11A were added at 1/500 dilution of ascites fluid. Plates were cultured as described previously. Proliferation was assessed after 48 h of culture by ³H-thymidine incorporation³⁷. The results shown represent the mean±1 s.d. of triplicate wells.

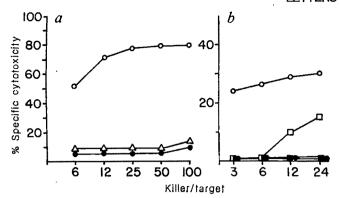

Fig. 3 Induction of cytotoxicity by OKT3 in CII cells. a, CII cells were added alone (\bullet), with OKT3 (O) or with OKT11A (\triangle) to 51 Cr-labelled U937 cells, and specific cytotoxicity was calculated (y-axis) at the indicated killer/target ratios. b, CII cells were added alone (solid symbols) or in the presence of OKT3 (open symbols) to 51 Cr-labelled U937 cells (circles) or 51 Cr-labelled K562 cells (squares). Methods. K562 and U937 cells were grown in culture medium containing

Methods. K.562 and U937 cells were grown in culture medium containing 10% fetal calf serum under culture conditions described in Fig. 1' legend. For each experiment, 10⁶ viable cells were removed from the cultures and treated with ⁵¹Cr-sodium chromate (Dupont), washed and placed (5,000 cells per well) in U-shaped 96-well plates (Costar). CII cells were added at the indicated killer/target ratios in a final volume of 200 μl. OKT3 and OKT11A (1/500 final dilution of ascites fluid) were added at the beginning of the assay. After 4 h of incubation of 37 °C in a humidified atmosphere containing 5% CO₂, 100 μl of the spun supernatants were removed and ⁵¹Cr content measured ³⁷. Specific cytotoxicity was calculated from the formula: specific cytotoxity = (experimental ⁵¹Cr release – spontaneous ⁵¹Cr release)/(total ⁵¹Cr release – spontaneous ⁵¹Cr release). Total ⁵¹Cr release was assessed by Triton lysis of the ⁵¹Cr-labelled cells.

alone proliferated. Since anti-T3 is also known to induce cytotoxicity in normal T cells, we studied its effect on the induction of killing by CII cells²⁹. We found that the addition of OKT3 to CII induced killing of ⁵¹Cr-labelled U937 macrophage targets (Fig. 3a). Untreated CII cells or CII cells treated with anti-T11 were not cytotoxic. In other experiments we found that anti-T3 induced CII cells to kill the natural killer cell target K562 (Fig. 3b). Taken together, these experiments demonstrate that antibody perturbation of the T3 molecule on CII results in the induction of immunological functions analogous to those observed in mature T lymphocytes.

Because the functional T3 molecule is physically associated with the T-cell receptor on mature T cells, it was of interest to determine whether the CII cells expressed mature $T\alpha$ and $T\beta$ mRNA, and to determine whether CII expressed Ty mRNA, known to be present in T4⁻T8⁻ murine thymocytes. Total RNA from CII cells as well as from thymocyte subpopulations (T4⁻T8⁻ and T4⁺T8⁺), mature T cells, B-lymphoblastoid cells and HeLa cells was assayed by Northern blotting procedures for hybridization to 32 P-labelled T α -, $T\beta$ - and T γ -specific complementary DNA probes (Fig. 4). HeLa cells and the lymphoblastoid cells did not express mature $T\alpha$, $T\beta$ or $T\gamma$ mRNA. In contrast, peripheral T cells, expressed the mature 1.7-kb $T\alpha$ mRNA and a mature 1.3-kb T β mRNA, but did not express T γ mRNA¹³. Freshly isolated T4⁻T8⁻ cells expressed Tγ mRNA as well as both the 1.3-kb mature T β mRNA and the 1.0-kb D-J(diversity-joining regions) β transcript. In addition, these cells expressed an immature 1.4-kb $T\alpha$ transcript but not the mature 1.7-kb $T\alpha$ mRNA¹³. The T4⁺T8⁺ thymocyte population, thought to contain cells at a more advanced stage of development, did not express Ty mRNA, but did express both the mature 1.3-kb $T\beta$ mRNA and to a lesser degree the 1.0-kb $T\beta$ transcript. We did not detect the 1.7-kb $T\alpha$ mRNA in the $T4^{+}T8^{+}$ population, but observed only the immature 1.4-kb $T\alpha$ transcript.

The CII cell line expressed high levels of $T\gamma$ mRNA but did not express the mature 1.3-kb $T\beta$ mRNA or the mature 1.7-kb $T\alpha$ transcript. However, CII cells did express the immature 1.0-kb $T\beta$ transcript and a faint band between 1.0 and 1.4 kb

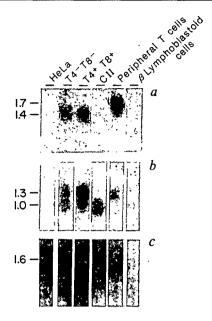

Fig. 4 Stage-specific expression of T-cell receptor (TCR) genes: a, α ; b, β ; c, γ . Approximately 6 μg of total RNA from each of the cell populations indicated was fractionated by formaldehyde/agarose gel electrophoresis, transferred to nitrocellulose or Nytran and assayed for hybridization to 32 P-labelled human $T\alpha$, $T\beta$ and $T\gamma$ cDNA probes (kindly provided by T.W. Mak and described elsewhere 6,38,39). Hybridization conditions were performed as described previously 40 .

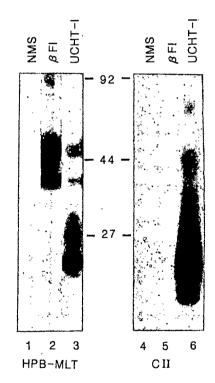

Fig. 5 SDS-PAGE analysis of T3 and T3-associated molecules from CII and HPB-MLT. ¹²⁵I-labelled detergent lysates from T-leukaemia cell line HPB-MLT and thymic clone CII were examined by SDS-PAGE. Immunoprecipitations were performed with nonspecific control antibody (normal mouse serum (NMS) in lanes 1 and 4, framework monoclonal antibody to the β -chain of the T-cell receptor (β FI) in lanes 2 and 5, and anti-T3 antibody (UCHT-1) in lanes 3 and 6 (ref. 29)).

anti-T3 antibody (UCHT-1) in lanes 3 and 6 (ref. 29)). Methods. 125 I-labelling was performed using the lactoperoxidase technique. Following radiolabelling, 10^7 lymphocytes were solubilized in Tris-buffered saline (pH 8) containing 1% Triton X-100. Lysates were immunoprecipitated using 1% I NMS, 1% pf I monoclonal antibody or 1% UCHT-1 monoclonal antibody. Immunoprecipitated proteins were resolved by SDS-PAGE (10.5% acrylamide) and radiolabelled species were visualized by autoradiography as described previously 14 .

which may correspond in part to the immature 1.4-kb $T\alpha$ transcript. Taken together, these data suggest a developmental progression of human $T\alpha$, $T\beta$ and $T\gamma$ gene expression similar to that observed in murine thymocytes, with γ genes expressed earliest, followed by β and then α gene expression^{13;15-17}. In this light, CII cells represent an early stage of thymocyte development in which γ genes are expressed in the absence of mature α and β gene expression.

The above data demonstrate that T3 surface expression in CII occurs in the absence of the expression of mature $T\alpha$ or $T\beta$ genes. Therefore, it was important to determine whether the T3 molecule on CII cells was physically associated with other surface proteins. For this, we immunoprecipitated 125 I-labelled surface proteins with anti-T3 as well as with antibodies to framework determinants of the β -chain Immunoprecipitated proteins were analysed by SDS-polyacrylamide gel electrophoresis (PAGE) under reducing conditions (Fig. 5). Immunoprecipitation of CII by anti-T3 revealed a T3 molecular complex (18-28K) that co-precipitated with two additional bands which migrated at 44K and 62K (Fig. 5, lane 6). In contrast, no bands were seen when CII was immunoprecipitated with β F1 (Fig. 5, lane 5). Immunoprecipitations of the control mature HPB-MLT cell line with anti-T3 revealed, as described previously, a T3 molecular complex co-precipitating with bands migrating at 40K and 49K (Fig. 5, lane 3)14. In addition, immunoprecipitation of HPB-MLT with BF1 revealed the 49K and 40K bands, representing the T α and T β chains¹⁴.

Our data demonstrate that the functional T3 molecule on the CII cells, although not associated with the $\alpha\beta$ heterodimer, is associated with a novel heterodimer of 44K and 62K. This structure is not seen on HPB-MLT cells (Fig. 5, lanes 2, 3) and has not been identified previously on human thymocytes or mature T cells. The finding of high levels of Ty mRNA expression in CII raises the possibility that one of the subunits of the 44/62K structure on CII could be encoded by the Ty gene. However, definitive designation of one of the subunits as a γ peptide must await amino-acid sequence analysis and comparison with deduced T γ protein sequence from CII T γ cDNA.

Surface expression of T3 is thought to mark a mature stage of T-cell development, and recent studies have suggested that surface T3 expression may depend on T α and T β expression^{26,31}. Our studies show definitively, however, that T3 can be expressed on immature thymocytes lacking $T\alpha$ and $T\beta$. Nevertheless, the concept that expression of surface receptor molecules may be essential for T3 surface expression may be correct, as CII cells do express a T3-linked 44/62K structure. Our studies, showing that antibodies to the T3 molecule associated with this heterodimer induce proliferation, IL-2 release and cytotoxicity, strengthen this idea by suggesting that the T3-44/62K complex on CII is functional. It has been speculated that precursor thymocytes may bear self-MHC receptors involved in the selection of the mature T-cell receptor repertoire intrathymically^{13,15,32,33}. If the CII cells described here do express self-MHC receptors, a candidate structure for this receptor is the T3-44/62K complex.

It is noteworthy that the 44/62K structure is not coimmunoprecipitated by anti-T3 antibodies from mature T cells¹⁴. This finding does not preclude its presence in a non-T3-linked form. Conceivably, mature T cells express a non-T3-linked 44/62K receptor, which might bind self-MHC molecules and participate in recognition of the antigen-MHC complex along with the T3-linked T-cell receptor. This hypothesis would permit independent interactions of the non-T3-linked 44/62K receptor with self-MHC. Such interaction would not necessarily induce autoreactivity because the T3 molecule may be essential for signal transduction26

We thank Dr T. W. Mak for $T\alpha$, $T\beta$ and $T\gamma$ cDNA probes and Dr F. Beverley for UCHT-1 monoclonal. Supported by NIH grants AI 14969 and AI 20698 to L.C.

Note added in proof: We have now immunoprecipitated solubil-

ized and 125 I-labelled proteins from C2 using anti-T3 and the anti-v-chain sera described by Brenner et al. 30. Immunoprecipitated proteins were analysed by SDS-PAGE under reducing conditions. The anti-y sera identifies the T3-associated 44K protein in CII.

Thy-1 functions as a signal transduction molecule in T lymphocytes and transfected B lymphocytes

Richard A. Kroczek, Kurt C. Gunter, Ronald N. Germain & Ethan M. Shevach

Laboratory of Immunology, National Institute of Allergy and Infectious Diseases, National Institutes of Health, Building 10, Room 11N311, Bethesda, Maryland 20892, USA

Thy-1, a glycoprotein of relative molecular mass 25,000 (25K), is a major constituent of the cell surface of mouse thymocytes, peripheral T cells and neurones1. In man, Thy-1 is present on neurones and on a small percentage of thymocytes, but is absent from peripheral T cells2. The amino-acid3,4 and complementary DNA⁵⁻⁷ sequences of Thy-1 indicate that it has a structure similar to an isolated V (variable region) domain of immunoglobulin⁴. Although the function of Thy-1 is unknown, the ability of different anti-Thy-1 monoclonal antibodies to activate murine T cells8, induce functional changes in neuronal cells in vitro 10 suggests that Thy-1 is involved in transmembrane signalling. We now show that crosslinking of murine Thy-1 triggers a rapid rise in the cytoplasmic free calcium concentration ([Ca2+]i), not only in murine T cells and Thy-1.2-transfected human T cells, but also in murine Blymphoma cells transfected with the murine thy-1.2 gene. These results indicate that the generation and transduction of the signal leading to the rise in [Ca2+]; is independent of the T-cell receptor and other T-cell-specific molecules. The preservation of the [Ca2+]1modulating function of Thy-1 in various lymphoid cells of two species further suggests that the necessary signal either originates in the Thy-1 molecule itself or is generated in concert with a highly conserved molecules(s) associated with Thy-1.

To define the cell surface and the intracellular requirements for signal transduction via Thy-1, several previously characterized cell lines which do not naturally express Thy-1, including the human T-cell tumour Jurkat E6.1 (ref. 11) and the murine B-lymphoma lines NBL.DUB¹², M12.4.1 (ref. 13) and WEHI 231 (ref. 14), were transfected with a murine genomic thy-1.2 clone. In Fig. 1, the fluorescence observed after staining of the murine T-cell hybridoma P.4.4 (a) with the anti-Thy-1 monoclonal antibody 3H11 is compared with that seen after staining of the thy-1.2-transfected clones Jurkat J14C9 (b), NBL.23C5 (c), M12.46E5 (d) and WEHI.40C2 (e). Because volume measurements demonstrated a very similar cell size in the populations examined, the amount of Thy-1.2 expressed by the cells could be estimated from the degree of fluorescence observed. Compared with P.4.4 (100%), the highest levels of Thy-1 were found on NBL.23C5 (88.3%); lower amounts were seen on M12.46E5 (40.9%), J14C9 (31%) and WEHI.40C2 (8.9%). Although the thy-1.2-transfected cell clones were reactive with a large panel of anti-Thy-1 monoclonal antibodies, they failed to bind antibody G7, which is mitogenic for resting murine T cells8. The parental lines Jurkat E6.1, NBL.DUB, M12.4.1 and WEHI 231 showed no reactivity with any of the anti-Thy-1 antibodies tested (results not shown).

As a rapid rise in $[Ca^{2+}]_i$ is an early event in a large number of cell activation models¹⁵, including the activation of T cells¹⁶⁻²⁰, we measured $[Ca^{2+}]_i$ after crosslinking of Thy-1 on the surface of the transfected cell lines as well as on murine thymocytes, peripheral T lymphocytes and the T-cell hybridoma P.4.4. For these measurements we used the fluorescent indicator Quin-2, which is trapped intracellularly, binds Ca²⁺ with a 1:1 stoichiometry, and shows increased fluorescence on binding Ca²⁺ (ref. 21). The cells to be tested were first loaded with Quin-2, incubated with rat antibodies 3H11 and 3A7, which recognize independent epitopes on Thy-1 (ref. 22), and washed. The preincubation with the two monoclonal antibodies did not change the resting [Ca²⁺]_i (results not shown). The cells were then reacted with MAR 18.5, a mouse antibody to rat κ -chains which does not bind to human or murine T or B cells²³. Preincubation with two anti-Thy-1 monoclonal antibodies gave better quantitative results with thymocytes, normal T cells and the T-cell hybridoma P.4.4, whereas identical tracings were obtained when only one anti-Thy-1 monoclonal antibody was used for preincubation of Jurkat J14C9 and the B-cell lines NBL.23C5 and M12.46E5 (results not shown). The tracings of Quin-2 fluorescence observed after crosslinking of Thy-1 on the various cell populations are shown in Fig. 2. After the addition of MAR 18.5, a rapid rise in [Ca²⁺]_i was seen in murine thymocytes (Fig. 2a), normal T cells (b) and the T-cell hybridoma P.4.4 (c). A similar result was observed in the transfected human cell line Jurkat J14C9 (Fig. 2d). As J14C9 expresses the T3 complex, which is known to trigger a rise in [Ca²⁺]_i (ref. 18), we compared the effect of crosslinking Thy-1 with the effect of antibody OKT3 (ref. 24) in the Quin-2 assay; the response to OKT3 (Fig. 2e) was more rapid and resulted in a greater rise in [Ca2+], which then reversed more quickly.

When the Thy-1 molecule on the transfected B-cell lines was subjected to the same crosslinking procedure using monoclonal antibodies 3H11/3A7 and MAR 18.5, both NBL.23C5 (Fig. 2f) and M12.46E5 (Fig. 2g) demonstrated a rapid rise in $[Ca^{2+}]_i$. In contrast, WEHI.40C2 (Fig. 2h) failed to respond in analogous experiments. As a positive control, the addition of a purified anti-IgM antibody preparation, which is known to increase $[Ca^{2+}]_i$ by crosslinking surface immunoglobulin²⁵, gave a positive signal in all three transfected B-cell lines (Fig. 2k-m). In general, anti-IgM antibodies produced a higher initial rise in $[Ca^{2+}]_i$, but crosslinking of both surface immunoglobulin and

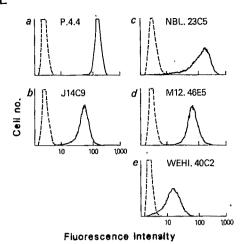

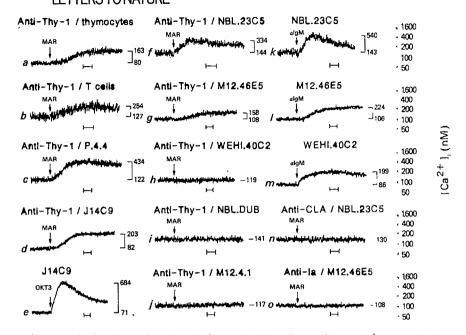

Fig. 1 Flow microfluorimetric analysis of Thy-1 expression on the T-cell hybridoma P.4.4 (a) and on the thy-1.2-transfected cell lines J14C9 (b), NBL.23C5 (c), M12.46E5 (d) and WEHI.40C2 (e). Cells (1×10^6) were preincubated with excess anti-Thy-1 antibody 3H11 (ref. 33) (-) for 30 min at 4 °C, then washed three times with Hanks' balanced salt solution containing 0.1% NaN3 and 3% fetal calf serum. The cells were then stained with excess fluorescein isothiocyanate (FITC)-conjugated antibody MAR 18.5, which is specific for rat κ light chains²³, and 3×10^4 viable cells (as determined by propidium iodide exclusion) were analysed on a fluorescence-activated cell sorter (FACS II: Becton Dickinson). The broken line indicates background fluorescence with FITC-MAR 18.5 alone. Control staining of the parental (Thy-1-negative) cell lines Jurkat E6.1, NBL.DUB, M12.4.1 and WEHI 231 yielded results identical to the FITC-MAR 18.5 background of the respective transfectants (results not shown). Measurements of cell volume were performed on a cell analyser (Becton Dickinson). Calculations indicated a cell-surface ratio for P.4.4/J14C9/NBL.23C5/-M12.46E5/WEHI.40C2 of 1:1.41:0.93:0.96:0.85. The T-cell hybridoma P.4.4 was produced as described previously³⁴; thy-1.2transfected cell lines were produced as described in detail elsewhere²⁷. Briefly, an 8.2-kilobase (kb) EcoRI fragment containing the complete thy-1.2 gene was cloned into the EcoRI site of the pSV2gpt vector³⁵. Spheroplasts were produced from Escherichia coli HB101 and fused to Jurkat E6.1 and to the murine B-cell lines. Expression of the Ecogpt gene in transfected cells enabled selection and long-term maintenance of cells in the presence of mycophenolic acid, hypoxanthine and xanthine. Colonies which grew out of selection were cloned at limiting dilution and analysed for Thy-1.2 expression by flow microfluorimetry.

Thy-1 produced a similar sustained elevation of [Ca²⁺]_i. The reason for the differential behaviour of WEHI.40C2 remains to be determined, but it is possible that the relatively low expression of Thy-1 on the surface of this cell line (see Fig. 1) prevented an effective crosslinking of the bound anti-Thy-1 monoclonal antibodies by MAR 18.5.

Several control experiments were performed in order to rule out nonspecific effects of the crosslinking procedure on [Ca²⁺]_i. First, when the parental (Thy-1-negative) lines of the responsive transfected T- and B-cell lines were preincubated with antibody 3H11 or 3A7, washed, and then reacted with MAR 18.5, no increase in [Ca²⁺], was seen in NBL DUB (Fig. 2i), M12.4.1 (Fig. 2j) or Jurkat E6.1 (result not shown). Second, a number of monoclonal antibodies to other cell-surface antigens present on the cell lines were subjected to crosslinking with MAR 18.5 in the Quin-2 assay; no elevation of [Ca²⁺]_i was seen in either NBL.23C5 preincubated with a monoclonal antibody to the common leukocyte antigen (CLA; Fig. 2n) or M12.46E5 preincubated with an anti-Ia monoclonal antibody (Fig. 20). Negative results were also observed when NBL.23C5 was pretreated with a monoclonal antibody recognizing H-2, and when M12.46E5 was pretreated with antibodies to H-2, CLA or B220. Furthermore, negative results were obtained with P.4.4 after preincubaFig. 2 Tracings of Quin-2 fluorescence representing [Ca²⁺]_i in Thy-1-bearing and thy-1.2-transfected cells. The scale for the ordinate has been standardized by appropriate optical reduction of the tracings; the scale bar in each record represents 1 min. a IgM, anti-IgM antibody.

Methods. In a modification of the method described by Tsien et al.²¹, the cells to be assayed (5×10⁶ ml⁻¹) were loaded in culture medium with a final concentration of 15 µM Quin 2-AM for 20 min. After loading, the cells were washed twice with Dulbecco's phosphate-buffered saline, resuspended in the same buffer to a concentration of 5×10⁶ ml⁻¹ and used immediately after equilibration at 37 °C for 5 min. Where indicated, Quin-2loaded cells (1×10^7) were preincubated with monoclonal antibody (250 µl of 1:10 ascites of 250 µl of purified antibody; 1 mg ml⁻¹) for 15 min at 37 °C and washed twice more. Fluorescence intensity was measured with a Perkin Elmer fluorescence spectrophotometer LS-5 (excitation 339 nm, emission 492 nm). The cuvette chamber was kept at 37 °C, and the cell suspension continuously stirred. After

a baseline had been established, antibody MAR 18.5 (1:100 ascites) or OKT3 (1:100 ascites) or anti-IgM antibodies (10 µg ml⁻¹) were added Maximum fluorescence (F_{max}) was determined by lysing the Quin-2-loaded cells with 0.1% Triton X-100. Minimum fluorescence (F_{min}) was obtained after addition of EGTA (4 mM) and sufficient Tris buffer to raise the pH to 8.3. Approximate values for cytoplasmic free Ca calculated using the formula: $[Ca^{2^{+}}]_{ix} = 115 \text{ nM} (F_x - F_{min})/(F_{max} - F_x)$ (ref. 21). The following antibodies were used for preincubation: 3H11 (Thy-1)³³, 3A7 (Thy-1)³³, M1.4/42.3.9.8 (H-2 common determinant)³⁶, M1/9.3.4.HL.2 (CLA)³⁶, FD441.8 (LFA-1)³⁷, M5/114 (Ia common determinant)38 and RA3-3A1 (B220)39. The affinity-purified anti-IgM antibodies (given by Dr Junichiro Mizuguchi) were prepared as described previously40.

tion with antibodies to H-2, CLA and lymphocyte function antigen (LFA-1) (results not shown). Thus, numerous lymphocyte surface antigens failed to act like Thy-1 in inducing a rise in [Ca²⁺]_i, demonstrating the specificity of the latter effect.

The ability of Thy-1 to act as a signal transducing molecule was first noted when it was recognized that anti-Thy-1 antibodies present in rabbit antisera to mouse brain were responsible for the T-cell mitogenic effects of such antisera²⁶. More recently, we and several other groups have confirmed and extended these studies by demonstrating that certain monoclonal anti-Thy-1 antibodies can activate resting murine T cells, as well as T-cell hybridomas and cytotoxic T-cell clones^{8,9}. Furthermore, we have shown recently that after crosslinking, a large number of unselected, non-mitogenic anti-Thy-1 antibodies (including 3H11 and 3A7) are capable of inducing a vigorous proliferative response in murine T cells and interleukin-2 (IL-2) production in thy-1.2transfected human Jurkat clones in the presence of phorbol esters; IL-2 production could be observed in murine T-cell hybridomas even in the absence of a co-stimulator^{22,27}. Our previous results, together with the present data, demonstrate that in every case in which crosslinking of Thy-1 elicited a rise in [Ca²⁺]_i, this was followed by functional responses in the T-cell populations studied.

The ability of crosslinked Thy-1 to trigger a rise in [Ca²⁺]_i in thy-1-transfected B cells clearly indicates that the signal delivered is independent of the T-cell antigen receptor and other T-cell-specific molecules. The preservation of the signalling function of Thy-1 in several lymphoid cell types of two species could be explained by a model in which Thy-1 associates, not only in murine B and T cells but also in human T cells and presumably in rodent and human neuronal cells, with a highly conserved molecule responsible for the rise in $[Ca^{2+}]_i$. Alternatively, the triggering signal leading to a rise in $[Ca^{2+}]_i$ may be generated by the Thy-1 molecule itself. Recent results indicate that Thy-1 is anchored directly to a cell membrane lipid, probably phosphatidylinositol^{28,29}. Whether this peculiar mode of membrane integration is related to the function of Thy-1 is at present unknown, but it is interesting to note that breakdown products of membrane phosphoinositides are involved in receptor-mediated signalling events, including changes in [Ca²⁺]; (reviewed in ref. 30).

The formulation of a hypothesis concerning the role of Thy-1 in the ontogeny and function of T cells is complicated by the differences in tissue distribution between species. The results of the present study are compatible with the view that Thy-1 has a critical role as an inducer of an alternative pathway of T-cell activation, in a manner similar to that proposed for the T11 antigen on human thymocytes and T cells^{31,32}. Thus, Thy-1 may represent a phylogenetically primitive pathway of cellular triggering which may have evolved prior to the antigen-specific receptor and which may function primarily in triggering thymocyte growth and differentiation. Whether this model is correct, and whether Thy-1 plays a similar part in transduction of intercellular differentiation signals in other Thy-1-bearing cell types, remains to be determined.

We thank David Scott for the NBL.DUB cell line, Art Weiss for the Jurkat subline E6.1, Linette Edison for the flow microfluorimetry studies, and Shirley Starnes for secretarial assistance. R.A.K. was supported by a grant from the Deutsche Forschungsgemeinschaft.

Human T-cell γ genes contain Nsegments and have marked junctional variability

The γ -chain genes are encoded by immunoglobulin-like gene segments in germline DNA which rearrange during the somatic development of T cells to form an active gene¹⁻⁷. The protein produced by these genes has not been identified and the diversity of the proteins that the genes can express has not been determined. We expect that the diversity of expressed y-chains is produced by the same three mechanisms that produce diversity of other immunoglobulin-like genes: (1) germline variable (V) and joining (J) region repertoires; (2) somatic mutation; and (3) junctional diversity^{8,9}. To define the contribution of each of these mechanisms to the generation of γ -chain diversity, several γ -chain complementary clones and rearranged γ -chain genes have been characterized. Most of these clones seem to encode a defective y-chain, the variable- and constant-region portions being joined such that they would not be translated in the same reading frame. Here we report that the germline J-region diversity of the human T-cell \gamma-chain is very limited and that somatic mutation does not contribute to the diversity of the γ -chains encoded by the cloned segments. However, the junctional diversity of these γ -chain genes is extensive. We suggest that N sequences (template-independent sequences) have been inserted enzymatically into all of the y-chain genes characterized.

The repertoire of germline V and J_{γ} segments encoded in the human genome is small. Recent studies have demonstrated that the human genome contains 12 variable-region segments,

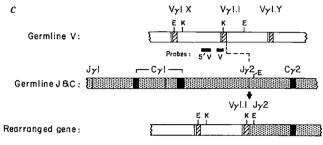

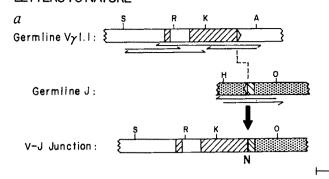

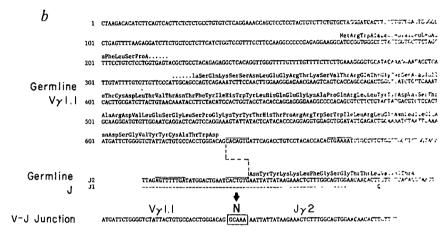

Fig. 1 Southern blots of germline and HPB-MLT $V_{\nu}1$ variable regions (a) and cloned $V_{\gamma}1.1$ (pgV $\gamma1.1$) and size-selected HPB-MLT genomic DNA (b). a, B-cell (Epstein-Barr virus-transformed B-cell line, LAZ 509) and HPB-MLT T-cell line DNA was digested with EcoRI, size fractionated on a 0.9% agarose gel, transferred to nitrocellulose and hybridized to a ^{32}P nick-translated variableregion probe from pTy-1 (ref. 12). The rearranged fragment was identified by its hybridization to both V and J probes. Samples were run on the same gel, fragment sizes were determined by co-migration with γ DNA digested with HindIII. b, Plasmid pgV γ 1.1 contains a 7.5-kb EcoRI fragment which hybridizes to the V probe, and was cloned into SP6 from an EMBL 3A human placental library using standard techniques¹². HPB-MLT DNA was digested with EcoRI and size fractionated on a preparative 0.8% agarose gel¹²; the fraction which contained the rearranged fragment was identified by hybridization to a genomic J probe. pgVy1.1 DNA was digested with KpnI and electrophoresed on the same 0.9% agarose gel with the EcoRI-digested size-selected HPB-MLT DNA (lane 1) and the size-selected DNA digested with KpnI (lane 2). DNA was transferred to a nitrocellulose filter and hybridized to 32 P-labelled 5' V probe (c). c, Variable- and constantregion exon arrangement was determined by nucleotide sequence analysis and hybridization to the cDNA pTγ-1. Variable-region exons are shown by hatching, constant exons are solid, the constant locus of the choromosome is stippled. Probes 5' V and V were isolated by cleavage of pgV γ 1.1 (ref. 12). Abbreviations: E, EcoRI, K, Kpn I. Scale bar, 1 kb.

making up four separate families (refs 6, 7 and W.S., T.Q. and J.G.S., unpublished results). At least six of the V segments can recombine with J segments encoded in the γ -chain constantregion locus (Fig. 1c and ref. 6). Two J segments were identified by restriction fragment analysis in the γ -chain locus. To determine the difference between the amino-acid sequences encoded by the two J segments and to define their contributions to the rearranged genes, we have determined their nucleotide sequences¹⁰. The J regions and 1,000 base pairs (bp) of flanking sequence were determined. The 49-bp J segments encode identical peptides (they differ by only 1 bp; Fig. 2b; ref. 7). Homology between the two loci extends outside the coding region with >95% homology over the 500 bp from the J segment in either direction. The finding of extensive homology between the human $J_{\gamma}1$ and $J_{\gamma}2$ indicates that the human constant-region locus has duplicated recently, since the divergence of mouse and human, and that the J_{γ} segment does not contribute to y-chain diversity.

Fig. 2 Restriction map and DNA sequence of germline $V_{\gamma}1.1$, $J_{\gamma}2$ (also $J_{\gamma}1$), and the rearranged V-J junction and N segment. a, Variable (図) and joining segments (図) are indicated in germline and rearranged configuration. The germline variable region and constant region (図) are joined by somatic recombination. Open arrowheads represent recombination signals; the restriction fragments used for nucleotide sequence analysis are indicated by horizontal arrows. Abbreviations: S, SacI; R, Rsal; K, KpnI; A, Sau3A; H, HindIII; O, Dral; N, N segment. b, Complete sequence of $V_{x}1.1, J_{x}1, J_{x}2$ and V-J junction as determined from sequence analysis of pgV γ 1.1, pJ γ 1, pJ γ 2 and cDNA pTy-1, respectively. Splice signals are indicated by dotted lines over appropriate nucleotides; recognition sequences for recombination are overlined. Nucleotides not encoded in germline V or J segments are boxed and labelled N. Scale bar in a, 100 bp.

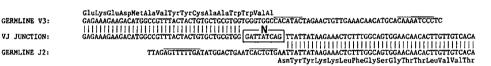

Fig. 3 Comparison of germline V, 3 and $J_{\gamma}2$ sequence with the V-J junction of cDNA pT γ -15. Heptamer and nonamer recombination sequences are overlined. Nucleotides not derived from germline sequence are boxed and labelled N. Vertical lines indicate identity of compared sequences.

The contribution of somatic mutation and junctional variation to the diversity of expressed γ -chains can be determined by comparing the nucleotide sequences of the germline V and Jsegments with the nucleotide sequence of the y-chain messenger RNA in particular T cells. We have previously obtained a full-length cDNA clone, pTy-1, which corresponds to y-chain mRNA from the T cell HPB-MLT (ref. 11). Southern blot analysis of germline (B-cell) DNA using the variable-region probe obtained from this cDNA clone indicated that the human genome contains a family of eight hybridizing variable-region gene segments (Fig. 1a), all except two of which have been deleted from the HPB-MLT genome (Fig. 1a, HPB-MLT). Most of the germline variable-region segments were cloned by screening an EMBL3A human placental library using the pTy-1 Vregion probe (data not shown and ref. 12). To determine which of these variable-region fragments was joined to the J segment to form the rearranged gene expressed in HPB-MLT, we compared the restriction enzyme map 5' of the rearranged γ -chain gene with the restriction enzyme map 5' of the germline variableregion genes (Fig. 1a and our unpublished results). Only one germline variable-region gene segment (designated $V_{\gamma}1.1$) yielded a 4.0-kilobase (kb) KpnI digestion fragment that hybridized to a 5' V probe and co-migrated with a fragment produced by KpnI digestion of purified rearranged fragment (Fig. 1b). Thus, $V_{\gamma}1.1$ is the germline variable-region fragment that underwent recombination with $J_{\gamma}2$ to produce the rearranged gene expressed in HPB-MLT (Fig. 1c).

Any differences between the nucleotide sequence of $V_{\gamma}1.1$ and the variable region utilized in HPB-MLT either occurred

by somatic mutation or are caused by polymorphic differences between the two individuals from whom the genes were obtained. To determine the extent of the differences between the two genes, we have determined the nucleotide sequence of $V_{2}1.1$ (Fig. 2a). We found that this germline variable-region gene is like other immunoglobulin and T-cell β -chain V segments and is encoded in two exons, a hydrophobic leader segment and a variable region. The conserved heptamer and nonamer sequences, thought to play an important part in somatic recombination and found 3' of all immunoglobulin-like V-region segments, are observed 3' of the $V_{\gamma}1.1$ variable region. The $V_{\gamma}1.1$ sequence was compared with the nucleotide sequence of the variable region expressed in HPB-MLT (Fig. 2b). Because there are no differences between the two variable-region genes, we conclude that somatic mutation has not occurred within this variable region since it underwent recombination to form the rearranged gene found in HPB-MLT. The sequence of a genomic rearranged γ gene utilizing this V region has been published recently and differs at a single nucleotide⁷. This difference could be a result of sequencing error, polymorphism or somatic mutation. If the difference is a product of somatic mutation, it is not important in generating y-chain diversity, since it is a silent mutation and does not affect the γ -chain amino-acid sequence.

The availability of germline V and J sequences as well as the nucleotide sequence of the cDNA expressed from the rearranged gene allows us to examine the mechanisms that produce diversity at the V-J junction. Comparison of the germline $V_{\gamma}1.1$ and $J_{\gamma}2$ sequences with the HPB-MLT cDNA sequence (Fig. 2h) indicates that 5 bp have been inserted between V and J during

Fig. 4 Junctional variability of rearranged γ genes. pT γ -1, pT γ -10, pT γ -15 are cDNAs, pT γ R4 is a rearranged genomic clone. λ S γ 12 and λ K γ 20 are rearranged genomic clones described in ref. 7. The nongermline nucleotides (labelled N segment) of pT γ -1, λ S γ 12 and pT γ -15 were determined by direct comparison with germline sequence (Figs

2, 3 and ref. 11). The variable regions have been aligned at the second conserved cysteine codon and $V_{\gamma}1.1$ used as a guide to predict the 3' end of the variable regions in pT γ R4 and pT γ -10. A predicted N segment was thus derived for pT γ R4 where germline sequence was not available. pT γ -10 and $\lambda K \gamma 20$ use the same V and J region but the sequences differ at the V-J junction, indicating that at least one of them has an N segment. Since the germline sequence of this variable region is not known, pT γ -10 has been arbitrarily chosen to represent a complete V region and the 3' end predicted by comparison with $V_{\gamma}1.1$. This conservative analysis results in a 5-bp N segment in $\lambda K \gamma 20$. It is possible that pT γ -10 contains up to 9 bp of N sequence. The entire germline J sequence is encoded in pT γ -1; J-segment bases missing in the other clones are indicated by blank spaces.

somatic recombination. New sequences of this type have been identified in rearranged immunoglobulin and T-cell receptor β -chain genes and result either from additional germline diversity (D) segments or sequences inserted enzymatically in a template-independent fashion $(N \text{ segments})^{8,9}$.

We have investigated whether there are additional base pairs between the V and J segments of other rearranged γ -chain genes by cloning a partial y-chain cDNA (pTy-15) from the T-cell line HSB-2, which would encode another defective ychain (Fig. 3). This cDNA contains a γ -chain V region which we have designated V_{x3} and which is a member of a different variable-region gene family (data not shown). The 3' end of the V₂3 gene was cloned on a 9.5-kb EcoRI fragment isolated from a subgenomic library produced from size-selected Jurkat DNA. Nucleotide sequence analysis of the germline V_r3 variable region and the HSB-2 cDNA (pTγ-15) identified no differences between the germline gene and the expressed cDNA in the coding portion. This sequence identity suggests that the rearranged y-chain genes found in mature T cells have not been subjected to extensive somatic mutation. However, during the recombination that joined this V to J, 9 bp have been inserted between the V and J segments.

To determine whether additional sequences are inserted between the V and J sequences of other rearranged γ -chain genes, we have isolated a rearranged genomic γ -chain gene (pT γ R4) and another cDNA (pT γ -10). The germline V-region segments that were involved in the formation of these rearranged γ -chain genes have not been sequenced. However, we can predict the location of the 3' end of the germline variable region by aligning the codons encoding the conserved cysteine residues (Fig. 4). Thus, using $V_{\gamma}1.1$ as a guide, this analysis predicts the presence of a 13-bp additional sequence in one rearranged gene and a 1-bp addition in the other (Fig. 4).

The additional bases inserted between the V and J segments are probably added enzymatically during site-specific recombination and represent N segments. Evidence for a D segment between V and J segments in the immunoglobulin heavy-chain genes and the T-cell antigen receptor β -chain genes has been obtained by the identification of recombined D-J segments in plasmacytomas or T cells¹³⁻¹⁵. The human γ -chain J segments rearrange to produce six different variable regions⁶. In more than 50 T-cell lines and tumours (corresponding to more than 100 rearranged chromosomes) no other rearrangements that might represent D-J recombination have been detected (ref. 6 and J. Greenberg, T.Q., J.G.S. and J. Kersey, unpublished results). Although the exact origin of N segments is not known, a model for their generation has been proposed which involves terminal transferase^{16,17}. In other immunoglobulin-like gene rearrangements, N segments have been described only in association with D segments^{8,9}. Rearranged immunoglobulin lightchain genes seem to use neither D nor N segments. The human y-chain gene provides the best evidence for an immunoglobulinlike gene that does not have a D segment but contains N segments.

Rearranged murine γ -chain genes have also been identified which contain two or three additional base pairs between the V and J segments^{2,3,18}. Although it has been proposed that these additional base pairs may represent a D or N segment, there is no evidence for a separate D segment. Although both the murine and human rearranged γ -chains have additional nucleotides separating the V and J segments, the rearranged human genes have considerably longer N segments than the murine genes (Fig. 4). The 9- and 13-bp N segments found in rearranged human γ -chain genes are as long as the total sequence found separating many T-cell receptor β -chain and immunoglobulin V and J regions^{8,9}.

The human γ gene can further produce junctional diversity by altering the site of recombination in V- and J-region segments. Eight bases at the 3' end of the germline $V_{\gamma}3$ segment are absent in the rearranged gene (Fig. 3), and up to eight bases are lost from the 5' germline J sequence during recombination (Fig. 4). Flexibility in the site of recombination is thought to be an important source of variable-region diversity among other immunoglobulin-like genes and apparently occurs in the formation of rearranged γ -chain genes.

An important feature of all four rearranged y-chain genes described here is that they are rearranged in a way that will not produce an active gene. However, Lefranc et al. have recently described two y-chain genes that have rearranged so that they encode productive γ -chain transcripts⁷. Comparison with the germline variable-region sequences presented here suggests that both of these genes have N segments inserted between V and J segments (Fig. 4). The apparently high rate (four of six) of ineffective γ -chain gene rearrangement may represent the high price paid to achieve such flexibility of V-J joining. Presumably, the defective γ -chain genes rearranged in many mature T cells are not functional and these T cells do not have a requirement for functional γ -chain expression. One possibility is that junctional variability represents a by-product of a mechanism of recombinational inactivation of the y-chain gene; that is, the y-chain genes might rearrange during development of the T cell to produce a functional y-chain and subsequently undergo a second rearrangement as a feature of terminal T-cell differentiation. We have noted previously the infrequent use of $C_v 1$ in T cells, and we suggest that functional rearrangements of $J_{\nu}1$ occur in early T cells and may be lost during somatic development.

The human γ -chain derives little combinatorial diversity from two virtually identical J segments, although the possibility of further diversity resulting from rearrangement to other J-C loci has not been excluded. There seems to be little somatic mutation in the genes that have been sequenced. However, significant variability is introduced at the V-J junction by N segments and variation in the V and J recombination site. These mechan-

187

isms appear to be more active in the human γ -chain locus than in the murine locus. Although the mechanisms by which Nsegments are inserted into the V-J junction are unclear, this region in immunoglobulin proteins plays a significant part in determining antigen-binding specificity¹⁹. Thus, we believe that the junctional variability of the y-chains will have an important role in determining their function in the immune response.

Newly replicated DNA is associated with DNA topoisomerase II in cultured rat prostatic adenocarcinoma cells

William G. Nelson*, Leroy F. Liu† & Donald S. Coffey*

DNA topoisomerases have been proposed to function in a variety of genetic processes in both prokaryotes and eukaryotes1-3. Here, we have assessed the role of DNA topoisomerase II in mammalian DNA replication by determining the proximity of newly synthesized DNA to covalent enzyme-DNA complexes generated by treating cultured rat prostatic adenocarcinoma cells with teniposide. Teniposide (VM-26), an epipodophyllotoxin, is known to interact with mammalian DNA topoisomerase II so as to trap the enzyme in a covalent complex with DNA⁴⁻⁹. We have found that the teniposide-induced trapping of such complexes requires MgCl₂, is stimulated by ATP and is inhibited by novobiocin. The formation of covalent complexes seems to be reversible on removal of teniposide. Furthermore, analysis of the covalent complexes formed between ³H-thymidine pulse-labelled DNA and topoisomerase II following teniposide treatment reveals a direct association of the enzyme with nascent DNA fragments. Our results suggest that DNA topoisomerase II may interact with newly replicated daughter DNA molecules near DNA replication forks in mammalian cells.

We assayed for the appearance of teniposide-induced covalent complexes between topoisomerase II and newly replicated DNA in cultured Dunning R3327-G rat prostatic adenocarcinoma cells. For this we used a potassium-sodium dodecyl sulphate (K-SDS) precipitation procedure specific for protein-linked DNA^{9,10}. Monolayer cultures of growing cells were pulse-

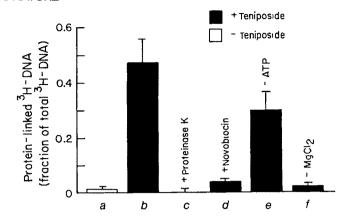

Fig. 1 Covalent linkage of pulse-labelled DNA to protein following temposide treatment requires an activity characteristic of mammalian topoisomerase II. The fraction of pulse-labelled ³H-DNA linked to protein (protein-linked ³H-DNA/total ³H-DNA) was determined for. a, control, lysates from cells incubated in buffer I without teniposide, b, teniposide, lysates from cells incubated with 20 µM teniposide; c, lysates from teniposide-treated cells that had been digested with 200 µg ml 1 proteinase K for 30 min at 50 °C; d, lysates from cells incubated with teniposide in buffer 1 supplemented with 2 mM novobiocin; e, lysates from cells incubated with teniposide in buffer I without ATP; f, lysates from cells incubated with teniposide in buffer I without MgCl₂. Protein-linked ³H-DNA fractions are expressed as means ± s.e.m.

Methods. Monolayer cultures of growing Dunning R3327-G rat prostatic adenocarcinoma cells were pulse-labelled for 90 s at 37 °C by exposure to ³H-thymidine (54 Ci mmol⁻¹) in complete medium (RPMI 1640 supplemented with 10% fetal calf serum, 25 nM dexamethasone, 100 U ml penicillin, 100 U mi streptomycin). Immediately after pulse labelling, the cells were permeabilized in situ by gently washing first for 5 min, and then again for 10 min at 4 °C with buffer E (0.5% Nonidet P-40, 10° glycerol, 10 mM NaCl, 5 mM MgCl2, 1 mM EGTA, 1 mM phenylmethylsulphonyl fluoride in 10 mM sodium phosphate, pH 6.5). In preparation for teniposide treatment, the cells were rinsed twice for 5 min at 4 °C with buffer I (100 mM NaCl, 5 mM MgCl₂, 1mM EGTA, 0.1 mM dithiothreitol, 0.5 mM ATP in 10 mM sodium phosphate, pH 6.5), buffer I without MgCl2, buffer I without ATP, or buffer I supplemented with 2 mM novobiocin. The rinsed, permeabilized cells were then incubated for 30 min at 37 °C in the same buffer with 0.2% DMSO (a) or with 20 µM teniposide and 0.2% DMSO (b f) before being lysed in lysis buffer (2% SDS and 10 mM EDTA in 10 mM Tris, pH 8.0). The lysates were subjected to the K-SDS assay^{9,10}. Briefly, for the non-denaturing K-SDS assay, 500 µl of 120 mM KCl were added to an equal volume of SDS lysate. The mixture was heated to 65 °C for 10 min, cooled at 4°C for 5 min and then centrifuged at 1,500g for 5 min at 4°C. The K-SDS-protein precipitate was recovered and washed by resuspending the precipitate in 1 ml of wash buffer (100 μg ml⁻¹ calf thymus DNA, 20 μg bovine serum albumin, 100 mM KCl, I mM EDTA in 10 mM Fris pH 8.0) and heating at 65 °C for 10 min. The wash mixture was then cooled at 4°C for 5 min and centrifuged at 1,500g for 5 min at 4°C. After five washes, the amount of protein-linked ³H-DNA was determined by dissolving the final precipitate in 1 ml of water before counting in 10 ml of Aquasol-2 (NEN). The total amount of ³H-DNA was determined by assessing the amount of trichloroacetic acid-insoluble ³H-DNA in the lysates.

labelled for 90 s with ³H-thymidine; in order to limit the ³Hthymidine pulse duration to 90 s, the cells were placed on ice and permeabilized immediatedly after labelling. The permeabilized cell monolayers were then treated in situ with teniposide in the absence of exogenous deoxynucleoside triphosphates before being lysed in SDS. When SDS lysates from these cell monolayers were subjected to the K-SDS assay, 3H-DNA was recovered along with the K-SDS precipitate (Fig. 1b). Digestion of the lysates with proteinase K reduced the amount of K-SDSprecipitable ³H-DNA by >99% (Fig. 1c), confirming the specificity of the K-SDS assay for protein-linked DNA. Markedly less topoisomerase II-linked ³H-DNA was detected when the topoisomerase II inhibitor novobiocin was included during teniposide treatment (Fig. 1d), while omission of teniposide (Fig. 1a), ATP (Fig. 1e) or MgCl₂ (Fig. 1f) from the incubation mixture resulted in a reduced amount of enzyme-linked ³H-DNA, as expected for a topoisomerase II reaction⁴ 6,8,10.

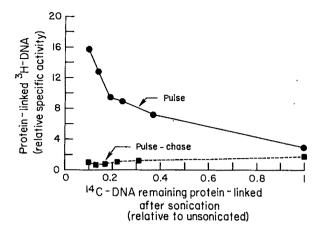

Fig. 2 Enrichment of newly replicated DNA with teniposide-induced covalent DNA-protein complexes. Cultured Dunning R3327-G rat prostatic adenocarcinoma cells that had been labelled for 72 h with 0.05 μCi ml⁻¹ ¹⁴C-thymidine (60 mCi mmol⁻¹) were incubated with 20 μCi ml⁻¹ ³H-thymidine (54 μCi mmol⁻¹) in complete medium for 90 s at 37 °C (pulse, •) or exposed to 20 μCi ml⁻¹ ³H-thymidine for 90 s and then incubated in 40 μM unlabelled thymidine in complete medium for 45 min at 37 °C (pulse-chase). Both pulse and pulse-chase labelled cells were permeabilized, treated with teniposide and lysed in lysis buffer as described for Fig. 1. Then, in order to progressively reduce the size of DNA remaining protein-linked, the lysates were sonicated for 0, 5, 10, 15, 20 and 30 s with a Branson Model W140 Sonifier at setting 2 before being subjected to the K-SDS assay as for Fig. 1. The specific activity of ³H-DNA in total DNA [(protein-linked ³H-DNA c.p.m./protein-linked ¹⁴C-DNA c.p.m.)/(total ³H-DNA c.p.m./total ¹⁴C-DNA c.p.m.)] was determined. This relative specific activity was plotted as a function of ¹⁴C-DNA remaining protein-linked after sonication (normalized to the unsonicated protein-linked ¹⁴C-DNA value).

Furthermore, protein-linked ³H-DNA complexes could be reversed by >60% after incubating the teniposide-treated monolayers in the absence of teniposide for 4 h at 37 °C. The time dependence of reversal (data not shown) was similar to that observed using purified topoisomerase II⁵.

³H-thymidine pulse and pulse-chase labelling experiments revealed that newly replicated DNA was specifically enriched within the teniposide-induced topoisomerase II-DNA complexes. Briefly, monolayer cultures that had been labelled previously for 72 h with ¹⁴C-thymidine were incubated with ³Hthymidine for 90 s (pulse) or exposed to ³H-thymidine for 90 s and then incubated with a 100-fold excess of unlabelled thymidine for 45 min (pulse-chase). Immediately following pulse or pulse-chase labelling, the cell monolayers were permeabilized, treated with teniposide, and then lysed in SDS. At this point, the SDS lysates were sonicated for various lengths of time in order to progressively reduce the average fragment size of DNA remaining covalently bound to topoisomerase II. The topoisomerase II-linked DNA fragments in the sheared lysates were then recovered usng the K-SDS precipitation procedure. The results of these experiments (see Fig. 2) indicated that as the amount of K-SDS-precipitable 14C-DNA was reduced by sonication, protein-linked DNA from pulse-labelled cells became progressively enriched in ³H-DNA (that is, the specific activity of protein -linked ³H-DNA relative to the specific activity of total ³H-DNA became >1). In contrast, protein-linked DNA from pulse-chase labelled cells was not enriched in ³H-DNA following sonication. In the absence of teniposide treatment, neither pulse-labelled nor pulse-chase labelled cells displayed any enrichment of ³H-DNA among protein-linked DNA, whether sonicated or not.

We believe that the association of pulse-labelled DNA with topoisomerase II-DNA covalent complexes may reflect a functional interaction of topoisomerase II with newly replicated DNA. However, another possible explanation for the observed

enrichment of newly replicated DNA with teniposide-induced topoisomerase II-DNA covalent complexes is that DNA at the replication fork might be more readily accessible for spurious binding to abundant nuclear proteins like topoisomerase II than is bulk nuclear DNA. We therefore treated pulse-labelled permeabilized cells with camptothecin, a plant alkaloid reported to trap covalent mammalian DNA topoisomerase I-DNA complexes¹¹, and found that camptothecin generated covalent protein-DNA complexes but failed to reveal any enrichment of ³H-DNA among protein-linked DNA after sonication.

Furthermore, the enrichment for pulse-labelled ³H-DNA with topoisomerase II-linked DNA was not limited to our permeabilized cell system. We found that for short ³H-thymidine labelling times, intact cells exposed to teniposide also contained protein-linked DNA enriched in ³H-DNA following sonication (Table 1). Cell monolayers that had been labelled previously with ¹⁴C-thymidine were incubated with ³H-thymidine for 5, 10, 20 and 30 min. In order to trap topoisomerase II-DNA complexes in the intact cells, teniposide was added to the ³H-thymidine incubation medium for the final 5 min of ³H-thymidine labelling. When the cells were lysed in SDS and sonicated, topoisomerase II-linked DNA enriched in ³H-DNA was recovered along with the K-SDS precipitate (see Table 1). The enrichment for ³H-DNA was greater for shorter ³H-thymidine labelling times.

Table 1 Teniposide treatment of intact cells reveals an enrichment of newly replicated DNA with covalent protein-DNA complexes

³ H-thymidine labelling time (min)	Protein-linked ³ H-DNA (relative specific activity)
5	19.1 ± 0.3
10	11.3 ± 0.3
20	7.7 ± 0.7
30	6.4 ± 0.1

Cultured Dunning R3326-G rat prostatic adenocarcinoma cells that had been labelled for 72 h with 0.05 Ci ml $^{-1}$ $^{14}\text{C-thymidine}$ (60 mCi mmol $^{-1}$) were incubated with 20 Ci ml $^{-1}$ $^{3}\text{H-thymidine}$ (54 Ci mmol $^{-1}$) in complete medium for 5, 10, 20 or 30 min at 37 °C. To trap topoisomerase II-DNA covalent complexes, teniposide was added to the $^{3}\text{H-thymidine-containing medium}$ to a final concentration of 20 μM (0.2% dimethyl sulphoxide, DMSO) for the final 5 min of $^{3}\text{H-thymidine labelling}$. Following $^{3}\text{H-thymidine labelling}$ and teniposide exposure, the cell monolayers were lysed directly in SDS lysis buffer and the SDS lysates were sonicated for 30 s with a Branson Model W160 Sonifier before being subjected to the K-SDS assay described in Fig. 1 legend. The specific activity of $^{3}\text{H-DNA}$ in total DNA was determined as for Fig. 2 and is expressed as the mean \pm s.d. The $^{3}\text{H-thymidine labelling}$ time dependence of this relative specific activity is given.

Topoisomerase II forms covalent complexes with DNA in the presence of teniposide such that each subunit (mammalian topoisomerase II is a homo-dimer) can be found in covalent linkage through a tyrosine to a 5'-phosphate on the cleaved substrate DNA^{5,10}. We sought to determine whether teniposideinduced covalent protein-DNA complexes were formed exclusively with unreplicated parental DNA near the replicating fork or whether nascent daughter DNA strands could be isolated with the complexes. In order to detect teniposide-induced complexes between topoisomerase II and nascent daughter DNA strands, 3H-thymidine pulse and pulse-chase labelled cells were permeabilized, treated with teniposide and lysed in SDS (as in Fig. 2). The SDS lysates were sonicated and then analysed by using the K-SDS assay under both denaturing (single-stranded DNA; lysates heated to 100 °C for 10 min) and non-denaturing (double-stranded DNA) conditions. We predicted that if covalent complexes were trapped near DNA replication forks, but only on unreplicated parental DNA, we should not detect denatured DNA enriched in ³H-DNA in sonicated lysates from pulse-labelled cells. We found instead that when lysates from

Fig. 3 Nascent DNA strands can be isolated in covalent linkage with topoisomerase II following teniposide treatment. Following sucrose gradient centrifugation, the fractions of the total protein-linked 3H-DNA (72-h label, a) and newly synthesized DNA (90-s label, b) recovered from each gradient were plotted as a function of fraction number (from the top). Arrows in a denote the position of the 2S (28 base pair, bp) and 13S (2,657 bp) markers determined by analysing aliquots from each fraction for ³²P c.p.m. Methods. Dunning R3327-G rat prostatic adenocarcinoma cells growing in culture were labelled with $20 \,\mu\text{Ci ml}^{-1}$ $^3\text{H-thymidine}$ (54 $\mu\text{Ci mmol}^{-1}$) for 90 s or with 1 $\mu\text{Ci ml}^{-1}$ $^3\text{H-thymidine}$ for 72 h in complete medium at 37 °C. Permeabilized monolayers treated with 20 μM teniposide (as for Fig. 1) were lysed in 1 ml of alkaline lysis buffer (0.2 M NaOH, 0.2 M NaCl, 10 mM EDTA). The alkaline lysates were carefully applied to 30-ml 5-20% sucrose gradients on top of 5-ml 50% sucrose cushions in alkaline buffer (0.1 M NaOH, 0.9 M NaCl, 10 mM EDTA) and centrifuged in an SW27 (Beckman) rotor for 15 h at 4 °C at 25,000 r.p.m. For DNA size markers plasmid pLY-1, a 2,679-bp pBR322 derivative, was digested with *EcoRI* and *ClaI*, and then end-labelled by fill-in with $[\alpha^{-3^2}P]$ dATP in the presence of unlabelled dGTP, dCTP and TTP using the Klenow fragment of DNA polymerase I (ref. 19), ²P-labelled 28- and 2,657-bp DNA fragments. s°_{20,w} Values for the fragments under alkaline sedimentation conditions were estimated to be 2S (for the 28-bp fragment) and 13S (for the 2,679-bp fragment), respectively²⁰. The labelled fragments were applied as internal markers in the gradient containing the alkaline lysate from the 72-h-labelled cells. After centrifugation 1.5-ml fractions were collected from the top of each centrifuge

tube by displacement with 70% sucrose. Fractions were neutralized by the addition of 0.1 ml 1.5 M HCl in 0.4 M Tris (pH 8.0). After the addition of 0.25 ml of 2×SDS lysis buffer and 0.25 ml of 240 mM KCl, 0.5-ml aliquots

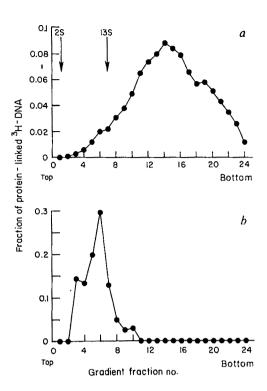

from each fraction were subjected to the K-SDS assay for protein-linked

DNA as described for Fig. 1 (with two washes).

teniposide-treated pulse-labelled cells were sonicated for 30 s (as in Fig. 2), the denaturing K-SDS assay revealed an enrichment of 3H-DNA among topoisomerase II-linked singlestranded DNA (13.7 \pm 1.3-fold) similar to that detected with the non-denaturing K-SDS assay for topoisomerase II-linked double-stranded DNA (13.4 ± 1.3-fold). Sonicated lysates from pulse-chase labelled cells failed to display any enrichment for ³H-DNA among topoisomerase II-linked DNA, regardless of whether the K-SDS assay was run under denaturing or nondenaturing conditions.

Further evidence that topoisomerase II might form covalent complexes directly with nascent DNA fragments in the presence of teniposide was provided by alkaline sucrose density gradient sedimentation studies. Pulse-labelled or uniformly labelled cells were permeabilized, treated with teniposide, dissolved in NaOH and then applied to alkaline sucrose gradients (see Fig. 3). After centrifugation, the gradient fractions were subjected to the K-SDS assay for protein-linked DNA. Similar to the findings of Chen et al.5, we found that most topoisomerase II-linked ³H-DNA from uniformly labelled cells treated with teniposide sedimented to a size of 25-35S (Fig. 3a). Topoisomerase IIlinked ³H-DNA from pulse-labelled cells treated with teniposide sedimented to a size (<12S) characteristic of nascent DNA chains (Fig. 3b).

Our results indicate that mammalian DNA topoisomerase II can be isolated in covalent linkage with newly replicated DNA molecules near the site of DNA synthesis, following teniposide treatment of permeabilized cultured rat prostatic adenocarcinoma cells. The close proximity of the teniposide-induced covalent complexes to the replicating fork suggests that DNA topoisomerase II may be actively involved in the replication of mammalian cell DNA. These findings are consistent with the identification of topoisomerase II as a component of the mammalian replitase12 malian replitase¹², a multi-enzyme complex responsible for DNA replication^{12,13}, and with the demonstration of topoisomerase II within the nuclear matrix¹⁴, the subcellular site for eukaryotic DNA synthesis15. An increase in topoisomerase II activity in rat liver following partial hepatectomy further supports a role for topoisomerase II in mammalian DNA replication¹⁶.

Previous studies on the role of DNA topoisomerase II in eukaryotic DNA replication have emphasized the importance of a topoisomerase II double-strand DNA passage activity in resolving the products of DNA synthesis prior to mitotic segregation¹⁷. However, our observation that mammalian DNA topoisomerase II covalent complexes may be located near the replicating fork suggests that the enzyme may also function during replication fork progression in mammalian cells. Cairns 18 recognized the need for an effective swivel in his description of the replication of covalently closed DNA molecules. We speculate that a mammalian DNA topoisomerase II, located near the replication fork in association with daughter DNA molecules, might be able to remove parental helical turns that have been passed through the fork to the daughter strands.

We thank Drs E. R. Barrack and G. L. Chen for helpful suggestions and comments, and R. Middleton for assistance in typing this manuscript. This work was supported by grants GM 27731 and AM 22000. W.G.N. is supported by the Medical Scientist Training Program Grant 5T32 GM 07309.

Nuclear magnetic resonance imaging of a single cell

James B. Aguayo*, Stephen J. Blackband, Joseph Schoenigert, Mark A. Mattingly‡ & Markus Hintermann‡

Nuclear magnetic resonance (NMR) imaging^{1,2} is now an established tool in clinical imaging and competes favourably with conventional X-ray computerized tomography (CT) scanning³. The drive behind NMR imaging has primarily been in the area of whole-body imaging, which has been limited clinically to fields of up to 1.5 T (60 MHz). It is recognized that there may be substantial advantages in obtaining images with sub-millimetre spatial resolution^{4,5}. Also, there may be benefits to imaging at higher fields, since the signal increases as the square of the magnetic field. Using a modified 9.5 T 89-mm-bore high-resolution NMR spectrometer, we have now obtained the first NMR images of a single cell, demonstrating the advent of the NMR imaging microscope. The NMR microscope is expected to have considerable impact in the areas of biology, medicine and materials science, and may serve as a precursor to obtaining such resolutions on human subjects.

The spectrometer was equipped with a set of magnetic field gradient coils with corresponding control units and power supplies capable of producing gradients for spatial delineation in excess of 20 G cm⁻¹. In addition, a radiofrequency (r.f.) modulator, a linear amplifier, waveform memories for gradient and r.f. control, and image display facilities were interfaced with the spectrometer. Radiofrequency excitation and reception were performed using a 5-mm horizontal solenoid. The studies presented here used a spin-echo imaging technique^{7,8}. The delay between the excitation and the acquisition of the spin-echo (TE) and the time between excitation pulses (TR) are given for each image in the figure legends.

The cells used in these studies were ova obtained from Xenopus laevis (African clawed toad) by standard surgical extraction techniques⁹. The ova were mechanically stripped of ovarian tissue and maintained in Barth's solution, and ova in different stages of oogenesis were placed in a 1.1-mm (inside diameter) tube and imaged. Figure 1 shows that the nucleus is clearly resolved, with heterogeneity in the cell cytoplasm seen as two regions of differing intensity corresponding to the animal and vegetal poles of the ovum. The differences in image intensity result from proton density variations, differences in relaxation times, or a mixture of the two. The water in the cell cytoplasm is distinct from the free water surrounding the cell, as has been suggested by some investigators¹⁰. The water signal from the nucleus is distinct from that of the cytoplasm and is indistinguishable from that of the free water surrounding the cell, suggesting that nuclear water is less strongly bound than cytoplasmic water. The signal-to-noise ratio of these images indicates that a greater spatial resolution can be obtained in similar times. To date, a resolution of 10×13 μm with a 250-μm slice width has been achieved (Fig. 2), although greater resolutions are expected to be possible. The nucleus of the ovum in Fig. 2 is clearly resolved, and a greater signal is obtained from the animal pole of the ovum than from the vegetal pole. Such data are obtained in acceptable experimental times (see Figs 1-4) and can be directly related to morphological regions within the cell.

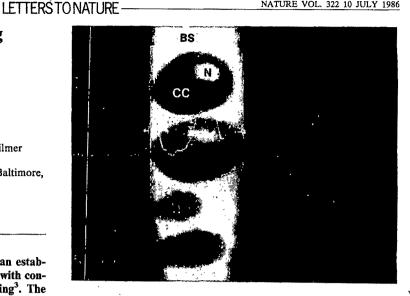

Fig. 1 NMR image of four ova from Xenopus laevis at different. stages of oogenesis. The image represents a slice 500 µm thick lengthwise through the tube containing the intact ova. The image matrix is 256×256, which corresponds to a spatial resolution of 16×27 μm. Zero-filling was not used in any of the following images as a means of improving resolution because we noted no significant improvement in image quality. A spin-echo pulse sequence was used with a TE of 16 ms and a TR of 1 s, resulting in an imaging time of 4 min and 16 s. The image shows the clear distinction between the cell nucleus (N) and the cell cytoplasm (CC). The profile across one of the cells demonstrates a signal-to-noise ratio for the nucleus of ~15:1. The cell was surrounded by Barth's solution (BS).

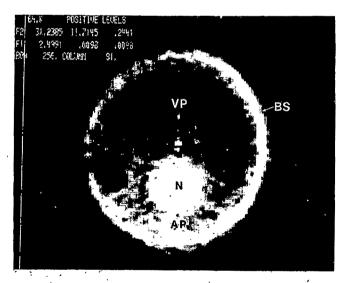

Fig. 2 NMR image representing a transverse slice across a glass tube containing a stage 4 X. laevis ovum; it has a spatial resolution of $10 \times 13 \,\mu\text{m}$ and a slice width of 250 μm . The spin-echo pulse sequence used a TE of 16 ms, a TR of 4 s, and produced a data array of 128 × 128. Four experiments were averaged and thus the total imaging time was 32 min and 8 s. Although the image is relatively grainy, the differences between the cell nucleus and different zones of the cytoplasm are easily discerned. VP, vegetal pole; AP, animal pole.

We have also been able to infer information about the chemical composition of the cell. A chemical shift artefact in the form of an adjacent, slightly overlapping image was noted in early cell experiments (Fig. 3). This artefact slowly disappeared as the cells remained in the imaging system for longer periods of time. Earlier data11 imply that this artefact is due to

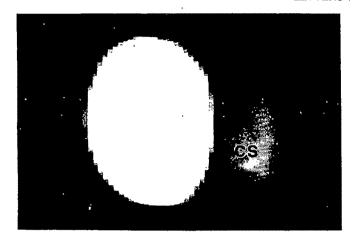

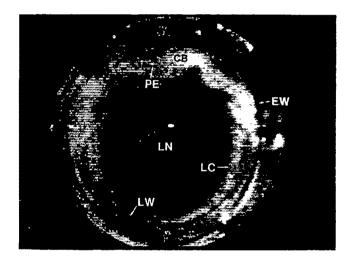

Fig. 3 (Left) NMR image showing a transverse section of a cell in a glass tube. The image acquisition parameters were the same as those of Fig. 1. The display constraints were adjusted so that low signal intensities can be easily observed. Under these display conditions the water signal from the cell appears as a solid white disk. To the right of this disk is a chemically shifted image (CS), which corresponds to the signal arising from the lipid content of the cell. The small dark area at the top of the chemical shift corresponds to the nucleus, indicating that there is little lipid within the nucleus.

Fig. 4 (Right) NMR micrograph of a mouse eye. The 256×256 data array has an in-plane resolution of 16×27 µm and a slice width of 250 µm. Only one data acquisition was used, with a TE of 16 ms and a TR of 2 s, resulting in an imaging time of 8 min and 32 s. The eye was placed in buffer solution within a 4.1-mm capillary tube. Considerable care was taken to ensure that there were no air bubbles around the eye, as these considerably distort the image. The image, from bottom to top, corresponds roughly to the eye, from side to side, although the presence of only one part of the ciliary body indicates that the imaging plane is tilted slightly from this equatorial plane. BS, buffer solution; LN, lens nucleus; LW, lens wall; LC, lens cortex; EW, eye wall; V, vitreous; CB, ciliary body. The dark patches in the surrounding buffer solution are due to extra-ocular material that remained after extraction.

the presence of lipid in the cytoplasm. Further studies should confirm the temporal dependence of this lipid. We speculate that the cell metabolizes these lipids during the experiment.

Figure 4 shows an image of a mouse eye to illustrate the clarity of images obtained at these high field strengths. The eye (~3.4 mm in diameter) was freshly extracted from a CD albino mouse. Structures within the eye are sharply resolved at a resolution of 16×27 µm, and the image definition is comparable to that of conventional NMR images. The resolution of this image is less than that of the ovum image in Fig. 2 because the object is larger; a larger matrix and hence a longer imaging time would have been required to obtain an image of the entire object. However, there is sufficient signal to obtain better resolutions on such samples, since both eye and cell images were obtained with an r.f. coil of the same diameter. The use of a zoom imaging technique should allow imaging of a small section of an object at high resolutions¹².

The slice widths within these images are considerably larger than the in-plane spatial resolution, primarily to reduce imaging times and improve the signal-to-noise ratio in the image. We

anticipate being able to use much smaller slice widths with these resolutions by efficient use and balance of imaging delays, r.f. coil design, imaging technique and higher fields. We note that in optical transmission microscopy the 'slice width' is determined by the physical width of the sample, which is often fixed, sectioned and stained. NMR imaging can be performed on intact living systems. No sectioning, fixing or staining was required to produce these NMR images and thus they are not subject to artefacts inherent in these procedures.

As expected, because the samples we studied were small, we observed no r.f. penetration problems. Also, no alterations in morphology were seen at this high field. Whether attenuation of r.f. energy at these frequencies will be a problem for larger samples and whether the high fields used are indeed harmful to living systems is unknown. Even if this should prove to be the case, we anticipate that a small-bore NMR microscope, as demonstrated here, will in itself prove to be a valuable tool in many spheres of science.

Several laboratories, including our own, have reported the synthesis and activity of certain low relative molecular mass inhibitors of mammalian serine proteases1-4, especially human leukocyte elastase (HLE, EC 3.4.21.37), an enzyme whose degradative activity on lung elastin has been implicated as a major causative factor in the induction of pulmonary emphysema⁵, and which is present in the azurophil granules of human polymorphonuclear leukocytes (PMN). Normally, these granules fuse with phagosomes containing engulfed foreign material (such as bacteria), and HLE, in combination with other lysosomal enzymes, catabolizes the particles^{6,7}. Under certain pathological conditions, however, PMN become attached to host protein (elastin fibres, basement membrane, connective tissue, immune complexes)8,9, and in response to this adherence, the granules may fuse with the PMN outer membrane and release their contents, including HLE, directly onto the tissue10 Besides emphysema, HLE may also contribute to the pathogenesis of disease states such as adult respiratory distress syndrome¹¹. and its potential involvement in rheumatoid arthritis 12 makes HLE inhibitors of considerable interest. It is known that cephalosporin antibiotics (for example, cephalothin (compound I, Table 2)) are acylating inhibitors of bacterial serine proteases which help synthesize the cell wall by performing a transpeptidation reaction on a peptidyl substrate bearing a D-Ala-D-Ala terminus¹³. We now report that neutral cephalosporins (that is, compounds not bearing a free carboxyl at position C-4) can be modified to become potent time-dependent inhibitors of HLE.

Cephalosporins bearing substituents in the 7α position are potent inhibitors of HLE (Table 2; details of the chemical synthesis of these compounds will be reported elsewhere). The corresponding 7β isomers are either weaker inhibitors or inactive. The preference for α over β substituents is perhaps due to the fact that HLE cleaves L-L-amino acid peptide linkages whereas the target enzymes for β -lactam antibiotics cleave D-D-amino-acid peptide bonds, and thus 7α -substituted cephems

Table 1 Kinetic constants for inactivation of HLE by substituted cephalosporins

Compound	$K_{i}\left(\mathbf{M}\right)$	$k_2 (\mathrm{s}^{-1})$	$k_2/K_i (\mathrm{M}^{-1} \mathrm{s}^{-1})$
XIII	$1.2 \times 10^{-6} \\ 1.8 \times 10^{-7}$	0.023	19,000
XXII		0.029	161,000

Rates of reaction versus time were measured at constant substrate and enzyme concentration, but varying inhibitor concentration. Data were computer fitted to the non-linear regression progress curve absorbance $= V_s \, r + (V_0 - V_s) \, (1 - \mathrm{e}^{-kt})/k + C$ (where $V_0 = \text{initial velocity}, \, V_s = \text{final velocity}, \, k = \text{observed rate constant}, \, t = \text{time and } C = \text{constant}$ integration), which assumes first-order enzyme inactivation. K_i and k_2 were calculated from a reciprocal plot of k versus inhibitor concentration.

may be better mimics of mammalian substrates. Further, we have found that the enzyme prefers smaller substituents in the 7α position, possibly because HLE cleaves proteins preferentially at sites where the P-1 (ref. 14) position is occupied by a relatively small alkyl substituent¹⁵. In the case of the alkyl ether series (compounds XIII → XIV → XV → XVI, Table 2), a rapid decrease in activity with increasing length of the alkyl group is observed. Branched groups (XVII) are also less active. The unsubstituted analogue (X) is inactive, but the 7α -fluoro derivative (XXI) is highly active, indicating that the inductive nature of the substituent has a strong effect on the rate of acylation. That inductive effects are not of overwhelming importance, however, is amply demonstrated by the fact that the 7α -ethyl analogue (XI) is a very potent inhibitor of the enzyme, almost as active as the isosteric 7α -methoxy derivative (XIII). Finally, aromatic rings can be tolerated by the enzyme; the 7α -phenyl analogue (XXIII) is roughly equipotent as an inhibitor to XIII, and in the ether series both XVIII and XX (but curiously not XIX) gave good inhibition of the enzyme.

The effects of modification of other parts of the cephalosporin nucleus have also been examined. With respect to the oxidation state of the sulphur, we have found that sulphones are generally the most active members of a series, with the (S)-sulphoxides and sulphides usually being an order of magnitude less active, and the (R)-sulphoxides being characteristically the least active of the series (compare compounds XIII \rightarrow XXV \rightarrow XXIV \rightarrow XXVI and XIV \rightarrow XXVIII \rightarrow XXVIII \rightarrow XXVIII \rightarrow XXVIII \rightarrow XXVIII \rightarrow XXVIII \rightarrow XXIX; Table 2).

Modification of the functionality at position C-4 has been studied extensively (compounds XXXI-XLII; Table 2). As noted earlier, the free acids are generally poor inhibitors of HLE. In fact, carboxylates even more remote from the nucleus (for example, compound XXXIX) also result in a loss of inhibitory activity. Considering that HLE is an endopeptidase that cleaves peptide linkages between non-ionic amino acids, the enzyme preference for neutral molecules (at least those not bearing a charge in close proximity to the active site) is understandable. Decreasing the steric bulk of the ester (XIII-> XXXIII → XXXII → XXXI) leads to some increase in activity. Incorporation of a benzene ring into the ester moiety (XXXIV) leads to a >10-fold enhancement in activity over XIII. Here again, placing a carboxyl at the C-4 position of the benzyl group yields a compound which is ~10-fold less active (XXXV), although still possessing substantial activity. The N-benzyl amide analogue (XXXVII) is ~100 times less active than the benzyl ester, but conversion of this secondary amide to a tertiary amide (XXXVIII) almost completely restores the inhibitory capacity of the molecule, leading to the interesting hypothesis that the s-cis amide conformation is required to fit the benzyl group appropriately into the active site. Note also that even a simple hydrogen at the C-4 position (XLI) still gives an entity with some inhibitory capability.

Most of the potent inhibitors in Table 2 cause time-dependent inhibition of HLE. (In Table 2 the compounds are evaluated according to their ability to cause 50% reduction in enzyme activity after an incubation period arbitrarily chosen to be 2 min. Greater inhibition is observed at longer times.) Preliminary kinetic data are consistent with a mechanism involving reversible complex formation followed by acylation of an active-site residue to produce the inactivated species (scheme 1). This

HLE was isolated as described previously^{2,3}. Purified HLE was assayed spectrophotometrically at 25 °C by continuous monitoring of the release of p-nitroaniline from Boc-Ala-Ala-Pro-Ala-p-nitroaniline at 410 nm. Incubation mixtures contained inhibitor, 0.2 mM substrate (both added in dimethyl sulphoxide; DMSO), DMSO (10% final concentration) and enzyme (added last) in 0.05 M trimethylaminoethanesulphonic acid, pH 7.5. The reaction was followed for 10 min and the rate after 2 min (r) was determined from the slope of the progress curve at that time. Per cent inhibition was determined by $100 \times [1 - (r_{\text{inhibitor present}}/r_{\text{inhibitor absent}})]$. IC₅₀ (concentration of inhibitor giving 50% inhibition) was determined from a plot of % inhibition versus log inhibitor concentration. Except for compounds which gave less than 50% inhibition at 20 μ g ml⁻¹, all inhibitors were studied over a concentration range that produced 15-90% inhibition.

inactivation of β -lactamases by various β -lactams^{16,17}. Table 1 shows kinetic constants for inactivation by compounds XIII and XXII. Both compounds are potent inhibitors (K_i values micromolar or less which rapidly and irreversibly inactivate the enzyme). Preliminary data suggest that certain other β -lactams may function solely as competitive (reversible, non-time-dependent) inhibitors of HLE. Further mechanistic details are being examined. Experiments are also under way to elucidate the structural features of β -lactams which are responsible for rapid inactivation.

Table 3 shows the relative inhibition of several different serine proteases by a representative set of cephalosporins. Most of the compounds in this series are excellent inhibitors of porcine pancreatic elastase (PPE) as well as HLE, and to a lesser extent α -chymotrypsin. This series shows no significant activity against trypsin or human cathepsin G, although some activity is seen against human thrombin, and one compound (XVIII) shows trace activity against plasmin. Interestingly, compound XX shows unusual activity against chymotrypsin, implying that an appropriate chain length has been achieved to allow the phenyl

^{*} Th, 2-thienyl.

[†] The compound is insoluble at higher concentrations.

Table 3 Selectivity of modified cephalosporins against various serine proteases IC., (up ml-1)

XX	2.5	0.5	< 0.5	≫20	≫20	»20	»20

Both elastases were assayed with 0.2 mM Boc-Ala-Pro-Ala-p-nitroanilide as described in Table 1 legend. Other proteases were assayed similarly using Ac-Ala-Ala-Pro-Phe-pNA (chymotrypsin), Cbz-Gly-Pro-Arg-pNA (trypsin and thrombin) and tosyl-Gly-Pro-Lys-pNA (plasmin) (all at 0.2 mM). Cathepsin G was assayed with 0.2 mM Boc-Tyr-p-nitrophenyl ester in 0.05 M PIPES buffer, pH 6.5, containing 10% DMSO at 25 °C by measuring the production of p-nitrophenol at 348 nm. IC₅₀ values were obtained as described for Table 1. HLE and cathepsin G (Cat G) were prepared as described previously^{2,3}. Porcine pancreatic elastase (PPE) was obtained from Sigma Biochemicals, bovine α -chymotrypsin (ChT) and bovine tryspin were obtained from Worthington, and human thrombin and human plasmin were obtained from Boehringer Mannheim. n.d., not determined

group to bind in the S₁ enzyme binding site.

One biological effect of elastase inhibitors is illustrated by the following observations. Microvascular haemorrhage can be part of an inflammatory response when PMN infiltrate inflamed tissue^{18,19}. Stetson and Good²⁰ postulated that this vascular damage may result from release of PMN proteases during phagocytosis. Argenbright et al.21 have shown that microvascular haemorrhage follows the intradermal injection of soluble human PMN granule contents into rabbits, and that this haemorrhage is dependent on HLE activity. Table 4 demonstrates that this

Table 4 Inhibition of microvascular haemorrhage by compound XIII

	Haemorrhage		In vitro activity	
	Blood vol./ skin site(µl)	% Inhibition	% Inhibition	
PMN extract +DMSO	86.5 + 12	,		
PMN extract +100 µg XIII PMN Extract	0.8 + 1.6	98	100	
+2.8 µg XIII PMN extract	22.1+10	75.	84	
+1.5 µg XIII	73.7 + 18	14	25	

Intradermal microvascular haemorrhage was produced in rabbit skin by the injection of components derived from human PMN granules. Haemorrhage was quantitated by measuring the 30-min accumulation of ⁵⁹Fe-autologous red blood cells in the injected skin sites. The data are expressed as the change in blood content as a result of PMN extract injection (for example, the $5.0 \pm 1.9 \mu l$ blood per site measured in vehicle injected sites has been subtracted from all other sites). Inhibition of haemorrhage was obtained by adding XIII directly to the PMN extract before injection. All sites received 0.4% DMSO. In vitro activity was determined by assaying a sample of PMN extract with and without addition of XIII against synthetic substrate according to previously published procedures15.

haemorrhage is inhibited by compound XIII, and further, that inhibition of haemorrhage correlates well with inhibition of HLE activity as measured in vitro.

Our study is the first reported demonstration that the appendages of a β -lactam nucleus, which has proved to be such an important source of bacterial enzyme inhibitors, can be modified to produce compounds that are potent inhibitors of human serine proteases. The implications of this work for further enzyme inhibitor design are clear, and we will shortly be reporting on the mechanism of this inhibition as well as our results with other B-lactam nuclei.

We thank Drs P. Davies, A. S. Rosenthal and T. Y. Shen for their support and encouragement in this work, Drs B. G.

Christensen, F. P. DiNinno, R. W. Ratcliffe, E. Walton and the staff of the Synthetic Chemical Research Department for aiding in the advancement of this research, Mr J. Smith for analytical support and Mrs Carol D. Babish for help in preparing this manuscript.

AMAZONIAN DYNAMICS

The collector that can't lose a drop, doesn't waste your time and won't cost a fortune.

nature

NATURE VOL. 322 17 JULY 1986

The Amazon basin rainforest in Madre de Díos. southeastern Perú. The meandering of the river crodes the old rainforest and creates point-bar deposits that promote primary succession. The river dynamics disturb all types of rainforest in the western Amazon as the forests are mostly growing on soils of floodplain origin. The resulting age heterogeneity contributes to the wide species diversity in the Upper Amazon. See page 254. The Author Index for volume 321 faces page 292.

A RANGE TO SUIT YOUR NEEDS

The Coulter family of Flow Cytometry Systems are easy to use, accurate and versatile. Combining an unparalleled choice of system sophistication and technical quality, they are the natural choice for the clinical and research laboratory. More than 500 EPICS systems are in use worldwide in these and many other applications.

The Coulter family comprises:-

EPICS C Series: simple to operate automatic systems

(shown above)

EPICS 54 Series: low-cost, versatile instruments for

routine and research use

EPICS 74 Series: high performance instruments with single or dual laser system capability.

EPICS 75 Series:

the most sophisticated system available offering single or dual lasers with an additional dye laser for three colour analysis/sorting.

All are backed up by Coulter Electronics superlative reputation for quality, service and reliability.

For further information and advice on the Coulter Flow Cytometry System to best suit your needs, write to or 'phone Coulter Electronics Ltd, Northwell Drive, Luton, Beds. LU3 3RH. Tel: (0582) 582442, Telex: 825074.

-GUIDE TO AUTHORS

Authors should be aware of the diversity of Nature's readership and should strive to be as widely understood as possible.

Review articles should be accessible to the whole readership.

Most are commissioned, but unsolicited reviews are welcome
(in which case prior consultation with the office is desirable).

Scientific articles are research reports whose conclusions are of general interest or which represent substantial advances, of understanding. The text should not exceed 3,000 words and six displayed items (figures plus tables). The article should include an italic heading of about 50 words.

Letters to Nature are ordinarily 1,000 words long with no more than four displayed items. The first paragraph (not exceeding 150 words) should say what the letter is about, why the studyit reports was undertaken and what the conclusions are.

Matters arising are brief comments (up to 500 words) on articles and letters recently published in *Nature*. The originator of a Matters Arising contribution should initially send his manuscript to the author of the original paper and both parties should, wherever possible, agree on what is to be submitted.

Manuscripts may be submitted either to London or Washington). Manuscripts should be typed (double spacing) on one side of the paper only. Four copies are required, each accompanied by copies of lettered artwork. No title should exceed 80 characters in length. Reference lists, figure legends, etc., should be on seperate sheets, all of which should be numbered. Abbreviations, symbols, units, etc., should be identified on one copy of the manuscript at their first appearance.

References should appear sequentially indicated by superscripts, in the text and should be abbreviated according to the World List of Scientific Periodicals, fourth edition (Butterworth 1963-65). The first and last page numbers of each reference should be cited. Reference to books should clearly indicate the publisher and the date and place of publication. Unpublished articles should not be formally referred to unless accepted or submitted for publication, but may be mentioned in the text.

Each piece of artwork should be clearly marked with the author's name and the figure number. Original artwork should be unlettered. Suggestions for cover illustrations are welcome. Original artwork (and one copy of the manuscript) will see returned when manuscripts cannot be published.

REGISTRATION INFORMATION

ADVANCE REGISTRATION — Mail the registration form along with a check (made payable to: **Miami Winter Symposia**) to our mailing address: Miami Winter Symposia, P.O. Box 016129, Miami, Florida 33101, U.S.A. Our street address is: Medical Research Building, University of Miami School of Medicine, 1600 N.W. 10 Avenue, Miami, Florida 33136.

The registration fee provides for: admittance to all scientific and poster sessions; scientific and publisher exhibits; the book of Short Reports, which will be given out at registration, a final program booklet which will be mailed in advance of the meeting; and, attendance at the social functions. A late registration fee of \$25 will apply to all registrations received after December 31. Cancellation retunds will not be honored if the request is received after December 31, and there will be a \$25 fee for any registration cancellation. Refunds will be mailed after the Symposium.

SYMPOSIUM REGISTRATION will begin in the Hyatt Regency Hotel/ University of Miami/James L. Knight International Center, level three, at 5:00 p.m. on Sunday, February 8. The scientific sessions will be held in the James L. Knight Theater, level three. Exhibits will be on level three, all located within the Center.

FREE COMMUNICATIONS will be held as poster sessions on Monday, Tuesday, and Thursday, February 9, 10, and 12, from 9:00 a.m. until 10:30 a.m. See instructions for submitting a poster.

ORAL PRESENTATIONS OF SELECTED POSTERS — Additional oral presentations will be selected from submitted posters.

WEDNESDAY, FEBRUARY 11 · DIFFERENTIATION

Howard Green, Harvard Medical School, Boston Involucrin: The Gene and The Protein

Bernardo Nadal-Ginard, The Children's Hospital, Boston Generation of Complex Contractile Protein Phenotypes through Promoter Selection and Alternative RNA Splicing

Tom Curran, Roche Research Center, Nutley Control of C-FOS Induction in PC12 Cells

William R. Jeffery, University of Texas, Austin Muscle Cell Determination in Ascidian Embryos

THURSDAY, FEBRUARY 12

CELL SURFACE & TISSUE INTERACTIONS

James A. Weston, University of Oregon, Eugene Environmental Regulation of Neural Crest Cell Behavior

William H. Kinsey, University of Miami School of Medicine, Miami Role of Tyrosine Kinases in Embryonic Development

William J. Lennarz, M.D. Anderson Hospital, Houston Cell-Surface Proteins in Gastrulation and Skeleton Formation

Masatoshi Takeichi, Kyoto University, Kyoto Cadherin Adhesion Molecules Associated with Animal Morphogenesis

Urs S. Rutishauser, Case Western Reserve University, Cleveland Developmental Biology of a Neural Cell Adhesion Molecule

MORPHOGENESIS

Susan V. Bryant, University of California, Irvine Cellular Interactions in Vertebrate Limb Patterning

David R. Soll, University of Iowa, Iowa City

Gene Expression and the Opposing Programs of Differentiation
and Dedifferentiation in <u>Dictyostelium discoideum</u>

Hans R. Bode, University of California, Irvine Patterning In Hydra

FRIDAY, FEBRUARY 13 . GENE THERAPY

This session is sponsored by Biosearch, Inc.

Richard C. Mulligan, Whitehead Institute, Cambridge, MA Prospects for Gene Therapy

Theodore Friedmann, University of California, San Diego In Vitro and In Vivo Models for Gene Therapy

TRAVEL INFORMATION

EASTERN AIRLINES is the official airline of the Miami Winter Symposia. Call Eastern's Special Convention Desk for 50% discounted fares. Eastern will handle your travel arrangements regardless of whether or not they service your city. Make your reservations by calling Eastern's toll-free number, 800-468-7022 (in Florida, 800-282-0244). Be sure to refer to the Easy Access number, EZ2P9, when speaking with the Eastern agent. You can have your travel agent write your ticket, or have Eastern send it to you along with an invoice for payment. Or pay for the ticket by other convenient methods that Eastern can suggest. Eastern has made attending this meeting as simple as possible.

HOTEL INFORMATION

The Symposium and all other functions will take place at the Hyatt Regency Hotel / University of Miami / James L. Knight International Center, 400 S.E. 2 Avenue, Miami, Florida 33131-2197. Rooms have been reserved in the hotel for Symposium participants at rates that represent a considerable reduction below those normally prevailing. They are available only to Symposium registrants and accompanying members and only for the nights of February 7 – 13, inclusive. Please complete the hotel reservation form and mail it directly to the hotel.

THE 20th MIAMI WINTER SYMPOSIUM • FEBRUARY 8 – 12, 1988
Advances in Gene Technology: Protein Engineering
Hyatt Regency / University of Miami / James L. Knight International Center

If you desire information about this meeting, send your name and address to: Miami Winter Symposia, P.O. Box 016129, Miami, FL 33101, U.S.A., or call 1-800-MIAMI-87.

NATURE VOL. 322 17 JULY 1986

195

South Africa gets out of hand

The present sad condition of the Republic of South Africa is unlikely to last for very long. But the timescale of general impatience may be dangerously short.

WHAT can be done and what should be said about the growing crisis in South Africa? Nature has no competence in the matter, which lies outside the terms of reference implicitly defined by a readership of professional scientists. Of course, there are some aspects of the condition of South Africa on which science has a bearing. There can be no genetic basis for the inequitable and offensive system of apartheid, which is not to say that apparent differences in the attainment of different races may not be induced by the systematic social deprivation of one (or several) of them. It is also pertinent, as in the argument begun just under a year ago by the thoughtless Southampton organizers of September's World Archaeological Congress, that academics outside South Africa cannot ostracize fellow-intellectuals working at South African institutions without irreparably and permanently damaging the cause of international scholarship. But there are also some commonsense considerations that deserve more attention than they are being given.

Those outside South Africa wishing to encourage change should prudently begin with an assessment of the time over which their hopes are likely to be realized. The temptation is to miscalculate that the system of apartheid is so near collapse that only modest pressure from outside will send it tumbling. This is why the cry for general economic sanctions is now widespread, not merely from outside South Africa, but by many of the black leaders within the republic. But that underestimates the capacity for survival of the Nationalist South African government. One of the most distasteful features of the apartheid system is that many of the black workers on whom the economy depends belong titularly not where they work but to artificial living places many miles away, to which they are supposed to return when they are out of work. If sanctions were effective enough to hurt the economy of South Africa, the republic government would be acting within its own laws if it chose to send the unemployed off to their "homelands" to starve in obscurity. The process would be difficult but not impossible, and would buy more time. Is it possible that well-wishers outside South Africa have allowed their distaste of the present system to lead them to too sanguine a view of the weakness of a government whose determination is, in other connections, its hallmark?

But if not sanctions, what? That is the general dilemma. The simplest answer is "selective sanctions", by which is meant a variety of schemes ranging from the cancellation of permission for South African aircraft to land elsewhere to a collective decision not to buy South African exports of certain kinds, fruit for example. But if full sanctions would not produce the intended effect, can half-sanctions succeed? (A few symbolic actions might nevertheless be worthwhile.) The difficulty running through these tortuous considerations is the frustration of governments elsewhere that they have no obvious means except the passive device of sanctions legally to influence internal affairs in South Africa.

Luckily, that does not imply that nothing can be done. Although the international banking system has been quietly helping to bring about the "disinvestment" in South Africa for which well-wishers have been asking, would it not now make sense, as

a condition for the continued operation of South African companies as subsidiaries of companies registered elsewhere, that they should promptly follow employment practices of the kind that would be expected of them outside South Africa, treating people of different races on an equal footing and providing for the disadvantaged the kind of technical training that would allow them to function properly in their jobs? The cost could be high. but not necessarily greater than that of sanctions and certainly less than the cost of the international chaos that will supervene if South Africa falls apart. Indeed, it might even be worthwhile to encourage the South African subsidiaries of overseas corporations to break the apartheid laws, as Barclays Bank has just done by lending money to a black employee to buy a house in a district reserved for whites. When industrialized governments do not shrink from telling companies to instruct their overseas subsidiaries to which customers they may and may not sell high technology, why should they shrink from using this power constructively within South Africa?

Trouble on the farm

The problems now facing farmers will not go away overnight.

Most developed countries have long since been forced by economic reality to reduce the scale on which they maintain once-traditional industries such as shipbuilding and steel manufacture. In many places, farming will be the next in line. So much has been clear for several years, some would say decades. Much of the food that farmers in developed countries now grow with the crucial help of government subsidies could already be grown more cheaply elsewhere, in Australia, New Zealand, Argentina and Zimbabwe, for example. As time passes, the list of potential suppliers of temperate foodstuffs will be or could be increased by the addition of many now-developing countries, which would conform well with Adam Smith's principle that the economic use of resources requires a division of labour: in the modern world, some must grow food and others make computers.

That is what the textbooks say. The reality is very different. The subsidies industrialized governments pay their farmers, which have ensured over the years that the industrialized world is awash with food that impoverished nations cannot afford to buy, serve a multitude of functions, not all of them respectable, Occasionally, the old strategic argument still surfaces that a country less than self-sufficient in food production is vulnerable to starvation in time of war, but this can hardly carry weight when most governments fear that future wars will be over before most people know they have begun, and when government warehouses are in any case filled to the brim with food that nobody wants. The social argument, that the farming community is the repository of an invaluable tradition whose erosion would spell the loss of crucial elements in the constitution of advanced societies, contrasts oddly with the continual war between farmers and many of the societies in which they are embedded over environmental issues, for example. (Too often. farmers cut the figure of state-licensed vandals.) That farming is a social problem is, on the other hand, undeniable: the plight of farmers (and their banks) in the Middle West of the United States during the past two years is one vivid proof. The nub of the difficulty is that most industrialized governments, after decades of encouragement of increased farm production, now find themselves morally committed to a large group of people whose lives have been spent in farming, who have no wish to do anything else and who are not outstandingly fitted to do other things. Governments also recognize, of course, that farmers are also voters, often noisy.

This dilemma is nicely illustrated by the state of British farming. Last year was in many ways disastrous. The government's Annual Review of Agriculture 1986 (HMSO, Cmnd 9708), published at the beginning of the year, showed that as a consequence of the appalling weather, farm income fell in 1985 by 43 per cent compared with the previous year, which had been a good year. In a year when there were 240,000 farms in Britain (a steadily declining number), farmers and their spouses were left with a cash income of merely £1,154 million, just about half the total scale of subsidy for British farmers last year (£2,205 million) and even less than the proportion of the farming subsidy (£1,308 million) provided by the Common Agricultural Policy by means of which European farming is sustained at an uneconomically high level.

In 1985, in other words, it would have been cheaper for the British taxpayer merely to have provided farmers with the cash they are supposed to have earned from their farming operations and to have bought in their production from the huge stocks of food the Community has built up over the years. Yet farmers are plainly undismayed by this alarming calculation. Farmers spent more on new machinery and building than the cash that stayed in their pockets, while the price of farm land remained buoyant, as the real estate dealers say.

Can this state of affairs be allowed to continue? Common sense says no. Now even the British government seems to be having second thoughts. In the past few weeks, there have been repeated hints that the scale of traditional farming must decline. One common suggestion is that farmers must take to growing other things than the traditional crops, and that British farmers should in particular take to growing trees. The prospect is not cheerful. So long as the incentive is financial, the trees that farmers grow will be cheap and nasty (see Nature 322, 101; 1986) like those favoured by the Forestry Commission. Environmental conflicts are more likely to be sharpened than diminished in the process. But trees grow slowly, and will not provide the continuing employment that farmers have come to regard as their birthright, even though the taxation system could no doubt be modified in such a way as to put £1,000 million plus in their pockets every year. Why not instead bite the unpalatable bullet, and draw up a long-term strategy for the industry that will properly quantify the supposed non-economic benefits, set these off against the equally intangible but important disbenefits of enforced rural life, and declare that the time will have to come, some years from now, when farming will be run on economic lines?

Shutting barn doors

The consequences of the Chernobyl accident are about to become diplomatic, thanks to IAEA.

When the Soviet reactor at Chernobyl, north of Kiev, went out of control on 26 April, it quickly became apparent, in Sweden where the fallout was first detected and, then, elsewhere in Western Europe, that the formal arrangements for dealing with trans-frontier radioactive pollution are inadequate. At the outset, there was no obvious means by which the Soviet Union could be required to provide fuller information about the character and the scale of the release of radioactive material

from the Chernobyl reactor. (It is now clear that the Soviet officials in charge of the reactor were not themselves aware of what had gone wrong, and that they may even have concealed what they knew about the scale of the accident from Moscow.) Inevitably, the Soviet Union was subjected to a great deal of verbal drubbing from Western governments, many of them eager to complain that Soviet secretiveness, a long-standing nuisance, had become a danger to other people's lives. Yet, curiously, it has been overlooked that, for the past three years, the International Atomic Energy Agency (IAEA) at Vienna has been nursing a kind of international agreement on trans-frontier radioactive pollution. At a conference opening at Vienna later this month, the agency is hoping to turn its draft agreement into an agreement that will stick.

Before this laudable exercise is written off as an attempt to shut the stable (or barn) door after the horse has bolted, some consideration should be given to the complexity of the issues that will arise during the coming weeks. The starting-point for IAEA's conference is the set of recommendations produced in April 1984 on the management of nuclear accidents that might cause fallout beyond the boundaries of the states housing faulty reactors and other nuclear facilities. Sensibly, indeed inevitably, the experts concluded that there should be an element of planning in advance.

Each reactor operator should have a well-defined set of criteria for telling when an accident must be taken seriously, must tell the authorities in neighbouring states about these criteria and must then identify, also in advance, the nuclear installations that are potentially a source of international trouble. All that makes sense, as does the requirement that there should be identified communications links by which news of accidents may be signalled if and when they happen. What IAEA now seeks, in the chastened atmosphere after Chernobyl, is an agreement between its member states that these modest guidelines will be adopted. Whether it will succeed is another matter.

Here are some of the impediments to agreement at Vienna. In many places, the exact design of nuclear installations and even their intended function is still a secret, for either military or quasi-military reasons. The Soviet Union, which declares the nature of its operating reactors to IAEA as a matter of course, says little about its other facilities such as separation plants. France is similarly coy about the division between the civil and military aspects of its nuclear plants.

Other states such as India and Israel (both members of IAEA but non-signatories of the Non-Proliferation Treaty) think they have an interest in keeping their neighbours guessing about their nuclear programmes, believing that their own security will be enhanced if they can give the impression of being capable of making nuclear weapons. Such states will not readily fall in with the suggestion that they should disclose the nature of their nuclear installations.

But even elsewhere, where a state has nothing (or nothing much) to hide, there will be a profound reluctance to say in advance that this or that nuclear plant is in principle capable of going wrong, and of causing trouble to others. Indeed, it is easy to imagine how information of that kind could be used malevolently by those who believe that Chernobyl gives them a licence to halt the nuclear industry in its tracks.

So this month's meeting at Vienna is bound to be a tense affair. Even enlightened governments will be uneasy about the disclosures they will be asked to make. Yet their long-term interest is precisely the kind of undertstanding on the management of major nuclear accidents that IAEA's guidelines would set in place. If one consequence will be the abatement of senseless secrecy in the management of nuclear installations, that will be an uncovenanted benefit of what is, in any case, an essential measure. And the fear that too much openness will put too much ammunition in the hands of the anti-nuclear people is unreal; part of the trouble now is that too many authorities have been too secretive for too long.

European research

Framework programme poses political questions

It began to emerge clearly last week that the scale of the European Commission's new "framework programme" of cooperative research and development in Europe is so large that a phase of real interaction between international and national research policies in Europe is now beginning, with national programmes the likely "losers" as research becomes more international.

This internationalization of science seems to be becoming a particular possibility in Britain, where technology minister, Mr Geoffrey Pattie, said last week that he had "no trouble" with the content of the European Commission's 1987-91 "framework programme", the definitive version of which the Commission should place before member states in the next few weeks.

Pattie's support, though qualified when it comes to matters of scale, is significant because, in line with Britain's current presidency of the European council of ministers. Pattie will preside for the next six months over the research council. And Britain attaches "considerable importance" to concluding political negotiations over the content and financing of the programme by the end of this year, Pattie

Pattie is concerned, however, at the possible cost of the programme (earlier this year, the Commission was seeking a near tripling of present spending from the present 4,300 million European Currency Units'); he demands more critical preassessment and analysis of Commission projects and says a final decision on fund-

ing may go to cabinet level.

In fact, Pattie's concern reflects the wider issue: that the levels of research spending recommended by the Commission are at last reaching a politically noticeable level. From around 2 per cent of member states' net research and development budgets, the Commission has moved in its framework programme to nearer 4-6 per cent. In individual projects, the levels are even higher: in materials science, for example, where European national spending lags far behind that of the United States and Japan, initial Commission spending proposals in the framework programme reached a fifth of all European research. This seemed to be going well beyond the mere "catalysis" of European collaboration for which the European Commission has previously argued; and at these levels it has begun to be difficult even for enthusiasts of European collaboration - like Mr Pattie - to argue that European research programmes should l

not substitute for national research, but add to it. Increases in European programmes are in danger, in Britain at least, of causing reductions in corresponding national ones.

Thus, in money-conscious Britain, where many of the financial issues are clearest, Treasury sources stress that ministries benefiting from any substantial increase in Commission research funding by winning grants — will have to account for these receipts, and may have their national support commensurately reduced. This near-automatic system of "attribution" of Commission receipts could affect a number of national programmes, not least because British researchers appear to be particularly effective at winning Commission support: last year, Britain won 27 per cent of available Commission research funding, although the country pays only 20 per cent of the Commission's total budget. In research, Britain's receipts exceed "juste retour"

Paradoxically, however, this success of British scientists in winning funds from Brussels could in future be penalized by Treasury insistence on the attribution of receipts. Increases under the framework programme could thus conflict with the research of the Department of Energy, and particularly of the Department of Trade and Industry. The Commission's plan to boost its pilot-scale "stimulation programme" — which has successfully combined basic research groups in joint research throughout Europe - could result, under the Treasury attribution rules, in a commensurate decrease in the funds of the research councils, or the universities directly. Sir David Phillips, who is both chairman of the Advisory Board for the Research Councils (which distributes basic research funding in Britain) and a member of the CODEST scientific committee which advices the Commission on science policy, admits that "a key question" now is how far, and whether, national budgets should be cut to support European cooperation. This is why Pattie considers that finding the money for the framework programme may become an issue for the whole government.

The Treasury itself remains unconvinced by the Commission's arguments for an increase in research, and opposes Pattie's view that the framework should not substitute for national programmes. Pattie himself feels he unfortunately gets little help from the Commission — which however important the programmes proposed tends to argue by exhortation.

More detailed and precise arguments are necessary, Pattie says. The framework programme itself should therefore include an important element of assessment to ensure and detail the "effectiveness" and "relevance" of projects and to sharpen arguments for ministers.

Despite the drive for "effectiveness" of the framework programme, however, "flat out market considerations cannot be the order of the day". Pattie insists, because the research-oriented framework programme must take into account the needs of the smaller countries in Europe. These have felt neglected by the quite separate (non-Commission) Eureka technology programme, in which market forces are to the fore. But framework research should have a long-term relevance to European technological competitiveness. An increase in industrial participation, on a sliding scale, as Commission research projects developed, would sharpen Commission programmes Pattie suggested. It would help "to keep testing out the project on industry" and to "make people shape up". Robert Walgate

German universities

In the past fifteen years, federal and Länder (regional) governments have spent DM38,000 million to create an extra 300,000 places at West German universities. But the era of expansion is now near its end, according to the commission for university building.

In its sixteenth framework plan, published last week, the commission recommends that a further DM9,000 million be spent between now and 1990. High priority is given to the extension of natural science and engineering faculties, among them a new faculty of informatics in Karlsruhe, the next phase of the new Biozentrum in Würzburg and a new centre for interdisciplinary research in Frankfurt. The greater part of the money, however, will go for medical institutions and clinics.

The Federal Minister of Education, Dorothee Wilms, emphasized that the goal of 850,000 university places had not yet been reached, but would be brought close with the creation of another 20,000 places in the near future. Although there are now signs of a downward trend in the number of students entering university, there are still around 1.3 million students. far more than there are places. Students have grown accustomed to overcrowded lecture theatres without room even to sit on the floor and inadequate library and laboratory space. As the deputy commission head, Anke Brunn, pointed out, there is no sign of the feared "education catastrophe", the collapse of education due to excess student numbers.

Jürgen Neffe

Spain

More university reforms needed

Barcelona

THERE are said to be two national spectacles in Spain, bullfights and "oposiciones", the recruiting system for the civil service. It is a matter of discussion which one is the bloodier. Reforms in access to university and CSIC (Spanish Science Research Council) positions have modified the "oposiciones", but recent experience suggests that some of the most controversial elements of the system still exist.

Spanish professors and researchers in public institutions are considered as civil servants and therefore have permanent tenure, which tends to create lethargy in many Spanish institutions. That was certainly the opinion, before coming to power, of many members of the Socialist Party, now starting its second four-year term in Spanish central government. Recent regulations have led to invited professors and research staff recruited on short-term contracts. The reforms introduced in universities and in CSIC in the past four years have, however, maintained the traditional civil service system and the selection by "oposiciones"

The spectacle itself is much less colourful than it used to be. The "oposiciones", in the nineteenth-century tradition but modified in the 1930s during the Second Spanish Republic, used to be a series of public examinations, theoretical or practical, designed to choose the ablest candidate for the job. Now, a candidate has to pass only two examinations, one on his personal curriculum and the second on a subject related to his field of research. A committee formed for every position or groups of similar positions makes its decision by voting and without appeal. The committee can put any kind of questions to the candidate. In some cases, the experience may be traumatic for candidates, committees (which may sit for weeks before reaching a decision) and for departments.

The Law for University Reform has introduced two important modifications. One is that universities now have the right to appoint two of the five-member committee that selects the candidates; the other three members are chosen by a computer at random from the list of professors of the same field.

The second change is that university departments may propose a "profile" of the candidate. The experience of the past two years shows that the result has normally been to slant appointments to specific people already working in the same department. The actual result is an increase in in-breeding in university departments and many people are worried about the long-term consequences. Hundreds of new positions are being advertised as a

consequence of the Law of University Reform; for example, the Autonomous University of Barcelona has had nearly 300 new positions in 1986 alone. But the rules may be modified in the near future in the light of experience.

In CSIC, the system shows some important differences. On the one hand, positions are advertised once a year and relate to specific institutes and specific subjects; on the other hand, since last year, all committee members are appointed by the president of CSIC and often include members of university departments as well as CSIC staff. In each of the past two years, about 200 positions have been advertised, after a long time without openings. Last year around 400 candidates applied for the positions. In some fields such as molecular biology, there were four candidates for each position,

which means that in many cases only one candidate applied, or none. This result has been interpreted as showing the need for a long-term policy for recruiting research personnel and for attracting scientists now working abroad. New statutes for CSIC are expected to be issued before the end of this year that will include a different structure for research staff.

The "oposiciones" was a system designed more than a hundred years ago to make Spanish public administration more accessible. It has been widely recognized that a new system would be needed before the end of the twentieth century to select the appropriate people for research or universities. But the rules of Spanish administration are difficult to change, and the recent regulations have tried to adapt an obsolete system to modern Spanish society.

It is generally felt in universities and CSIC that further steps are needed in any case to achieve a flexible and efficient recruiting system for Spanish higher education and research. **Pedro Puigdoménech**

India

Space programme uncertainty

New Delh

INDIA is still not sure when or how to get its multipurpose Insat I-C satellite launched into geostationary orbit to provide continuity in its space-based meteorological, television and telecommunications services.

Under a contract with the US National Aeronautics and Space Administration (NASA), the satellite, along with an Indian payload specialist, was to have been carried by the space shuttle this month. The indefinite postponement of shuttle flights after the Challenger explosion, and uncertainty about the availability of the alternative Delta rockets, has upset the schedule of the Indian Department of Space (DOS).

According to DOS secretary Professor U.R. Rao, negotiations are now going on with the European Space Agency for Insat 1-C to be accommodated in one of the Ariane launches before the end of 1987. With Ariane solidly booked for the next two years, and with its own schedule upset by the failure of the Ariane-IV launch in March, it is likely that Insat 1-C may not leave the ground before 1988. India's only functioning satellite, Insat 1-B, has been taking the full work load since August 1983 after its companion, Insat 1-A, was disabled by on-board power failure. The US Ford Aerospace Corporation, which built the three satellites for India. has been asked to deliver a fourth, Insat 1-D, by 1988.

Continuity of the satellite service is important, for India now relies significantly on Insat 1-B for weather forecast, television broadcast and telephone links be-

tween remote places. The satellite provides 4,000 two-way telephone circuits and has helped to network India's 173 television and 91 radio stations, as well as beaming television programmes directly to 2,000 community receivers in villages and relaying educational programmes to 1,953 schools and 62 colleges.

Insat 1-B is the only geostationary satellite over the Indian Ocean providing meteorological images to the world, and duplicate Insat weather data are supplied daily to the United States. Apart from ensuring continuity of services, India is anxious to get Insat 1-C launched as soon as possible to avoid possible political complications arising out of delay in occupying the allotted slot in the geostationary orbit. India will continue to rely on foreign launchers, as it is unlikely to be able itself to put satellites into geosynchronous orbit before the year 2000.

Insat 1-C is not the only project beset by delay. The test flight of the Augmented Satellite Launch Vehicle (ASLV), designed to lift a 150-kg payload, was scheduled for last year but has yet to take place. The launch of an Indian-built remote-sensing satellite from the Soviet Union, scheduled for September this year, has been postponed. India's only operational rocket, SLV-3, has not flown for the past two years.

According to DOS, the destruction of major facilities at its east coast Sriharikota launch complex is one reason for the slowdown of space activities. The complex was damaged in a cyclone two years ago and plans are afoot to shift it to a safer location.

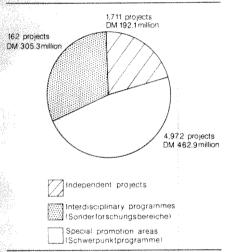

K.S. Jayaraman

The deutschmarks that count

Hamburg

THE annual meeting of the Deutsche Forschungsgemeinschaft (DFG), the West German Science Foundation, was held in Bonn last week. DFG's new president, Hubert Markl, pointed out that all DFG's activities were met with a budget of less than DM 1,000 million, just two per cent of the nation's research and development expenditure and, more significantly, only 60 per cent of the amount spent to subsidize the public theatres.

In 1985, DFG spent DM 982.6 million for the support of research and researchers, with 74 per cent going on personnel costs. Most of the money came from the federal government (DM 578.6 million) and the Länder (DM 397.4 million); expenditure was divided as below.

Markl rejected criticisms by the Wissenschraftsrat, the senior science advisory board, which had earlier said that doctoral education in West Germany is both too long and ineffective. Some 4,000 doctoral students are supported by DFG. Doctoral research is carried out in well controlled projects of quality, Markl said. He singled out for praise the contribution made by female scientists.

Chancellor Helmut Kohl made a speech in which he said that "quality and performance have reached a higher level", partly due to a retreat from the politicization of science. Despite increasing debate on the dangers of nuclear power and of science in general following the Chernobyl disaster, Kohl demands that politics should be kept out of science.

Hans-Werner Franke, the president of the Länder Ministers of Culture, Education and Church Affairs (Kultusministerkonfernz), demanded that the existing university system should be consolidated even with a decreasing student population. That may create a chance to switch some resources to research and to much-needed Jürgen Neffe reforms.

US technology

Making rivals work together

FROM the outset, the US Microelectronics and Computer Technology Corporation (MCC) was risky business. The plan to bring together arch-competitors in the semiconductor and computer industries in a cooperative research institute had no precedent, and even the Justice Department considered challenging the consortium's formation. After operations began in 1983, MCC president Admiral Bobby Inman struggled for over a year to bring first-rate talent to the facilities in Austin, Texas. Then a long silence ensued.

That silence has only recently been broken. MCC is now drawing cautious sketches of the technology it has transferred to its "shareholders" (the 21 companies that invest in and preside over MCC), Despite the slump in the computer industry, the consortium's membership has now more than doubled, and includes such giants as Honeywell, 3M and Control Data. MCC's budget has reached \$65 million a year and its staff is near capacity with 440 employees.

Seven programmes are under way, focusing on semiconductor packaging, software technology, computer-aided design and advanced computer architecture. Each company pays \$500,000 for a share in MCC, and then foots a portion of the bill for each programme in which it participates.

The shareholders also contribute staff - approximately 35 per cent of MCC's employees are "on loan" from shareholder companies. One representative from each company joins the board of directors and one the technical advisory board. Among developments that have already reached shareholders are a model for building expert systems, an editor to aid graphic design of semiconductor circuitry and an improved process for tapeautomated bonding which packs silicon chips tightly together on circuit boards and enables denser interconnections to be

The new technology is important, but what excites industry is whether the research structure of MCC can provide a new model. Inman says he and his managerial crew have vowed to minimize bureaucracy — "an everyday battle" — and to nurture the type of environment that encourages creativity. The three-level management hierarchy permits autonomy and quick decision-making within research ranks.

And MCC scientists are freed from the vagaries of market forces. The ability to provide stable funding and support is just part of the "psychic income" that keeps MCC laboratories alive, says vice-president and chief scientist John Pinkston.

MCC has invested heavily in its staff: \$20,000 to \$70,000 each for private computer workstations that in typical laboratories would be shared by up to four people. Although the aim is pre-competitive, collaborative research, the opportunities for collaboration are not unlimited. Because all programme information is considered proprietary unless declared otherwise, informal exchange between different programmes is discouraged.

Similarly, MCC scientists must bear in mind the expectations of their shareholders. Although they acknowledge that its goals are long-term, the shareholder companies are anxious to see MCC pay off. But shareholders have so far been reluctant to provide the brightest of their own staff for MCC.

Inman cites technology transfer as the most pressing problem confronting MCC. "We are delivering technology at a level of complexity that not too many of these companies are used to dealing with," he claims.

To enhance communication, quarterly updates and semi-annual research reviews bring shareholder and MCC scientists together regularly. Project teams throw "coming out parties" for newly-assembled technology packages, attended by all participating shareholders. Seminars and technical meetings take place frequently throughout the year. 3M and DEC have even moved their research and development headquarters to Austin.

Will MCC survive? Several industry consortia that have sprung up in MCC's wake pose no challenge, but the multi-billion-dollar budgets of the research and development teams at IBM and AT&T Bell Laboratories dwarf MCC's allotment. And the extent to which companies will capitalize upon MCC's legacy remains uncertain. Unequal gains could force out some shareholders and cause rancour

among those that remain.

Finally, the diversity of interests represented at MCC may curtail its expansion into key programmes that would help fill the gap created by such a shake-out. One example is Inman's drive for a manufacturing technology programme, which "raised a lot of welts" at a technical meeting last spring, according to one person who attended. The proposed programme is both too specific to draw broad support among shareholders, and too close to applied science to prevent competitive

But the adventurous spirit that created MCC may sustain it through the transitions ahead. With its unique position in industry research, the consortium has a rare opportunity to test alternatives.

Karen Wright

AIDS

US wins round in patent row

Washington

A US CLAIMS Court last week dismissed a suit brought by the Institut Pasteur in Paris against the United States — representing its National Cancer Institute (NCI) — over the development of a blood test for antibodies to the virus causing acquired immune deficiency syndrome (AIDS). Lawyers for the French research institute expressed confidence that the claims court decision would be reversed on appeal. But the legal issues raised by the Pasteur lawsuit may have a chilling effect on all international exchange of research materials.

Pasteur's case is based on a form signed by Mikulas Popovic, a colleague of Robert Gallo at NCI, when he accepted samples of a virus being studied at Pasteur by Luc Montagnier.

On 15 September 1983, Montagnier presented data at a Cold Spring Harbor symposium attended by Gallo and Popovic about a virus he called LAV. At the time, both Gallo and Montagnier were looking at a retrovirus as a possible causative agent for AIDS. On 23 September, one week after the Cold Spring Harbor meeting, Popovic signed a receipt accepting two isolates of LAV (Mkt-1B and JBB LAV) as well as anti-interferon sheep serum. The receipt stipulated that these materials would be used only for biological, immunological and nucleic acid studies, and would not be used for "industrial purposes without the prior written consent of the Director of the Pasteur Institute". NCI and Gallo have maintained that they adhered to those conditions. But Pasteur's lawsuit claims that Gallo and his associates used the LAV isolates in research that has since led to development of a commercial diagnostic test kit.

The claims court refused to decide the issue of whether the LAV isolates were used improperly. Instead, Judge James Merow based his ruling on whether or not the document Popovic signed constituted a contract with the United States. NCI argued that neither Popovic nor Gallo had authority to commit the United States to a binding contract. The court decided that even if the receipt did constitute a contract, the French institute had not followed appropriate procedures for settling contract disputes - in this case first submitting a claim to the Department of Health and Human Services — and dismissed the case.

James Swire, a lawyer for the Institut Pasteur, described the ruling as "roadblock, nothing more". Swire says it is a "sad day for international scientific research" when NCI disavows agreements of its principal investigators.

Reaction from the Department of

Health and Human Services was low key. A spokesman said the department was "pleased" by the court's ruling, and expressed hope that it would "provide impetus to resolving this matter". The claims court decision has no direct effect on a separate proceedings being conducted by the US Patent Office on a disputed patent claim for the AIDS antibody blood test (see *Nature* 320, 96; 1986). The Patent Office has awarded a patent to Gallo for his version of the blood test, but that patent could revert to Montagnier and the Institut Pasteur pending the outcome of the proceedings.

The claims court decision raises important questions about the legal standing of documents signed by researchers when exchanging research materials. J. Edward Rall, deputy director of the National Institutes of Health (NIH) for intramural re-

search, says collaborative agreements are usually entered into on a person-to-person basis. But Rall says most researchers at NIH are aware that there are certain documents they cannot sign.

In 1981, NIH associate director Philip Chen drafted a sample response for NIH scientists to use when requested to sign agreements accompanying cell lines. Researchers must reply that they cannot sign agreements containing waivers or indemnification agreements. They can, however, promise not to share the cell lines without permission from the supplying laboratory.

Scientists have not had to worry about the legal aspects of cooperation before. Both Chen and Rall say litigation is making some grow wary. Rall worries that if things grow worse lawyers may "subvert straightforward scientific collaboration" with legal arguments that will not be appreciated. "It may be that no one will sign anything any more", says Chen.

Joseph Palca

Eureka

Soviets feel left out of Europe

THE Eureka conference in London last month revealed a stance contrary to the Helsinki Accords, according to the official Soviet media. The "obvious tendencies" among participants to limit participation in scientific and technological cooperation to West European countries is seen, at best, as an impediment to the close contacts between countries irrespective of political orientation that were the goal of the Final Act, and at the worst as a means of diverting the supposedly peaceful Eureka programmes for military ends.

Much play has been made of an alleged French distinction between Eureka and the US Strategic Defense Initiative (SDI): SDI is a programme which has a civilian application, while Eureka is a civilian programme capable of a military application.

According to the official Soviet newsagency TASS, Western "political and industrial circles" have recently shown increased interest in the "military aspects of Eureka", while Aleksandr Bovin, a Moscow commentator, stressed that such "giants" as Siemens, Philips and Thomson want to take part simultaneously in both Eureka and SDI. There have been indications in the world press, Bovin said, that Bulgaria, Hungary, Czechoslovakia, Yugoslavia and East Germany are interested in working "within the Eureka framework", but the Western countries do not wish to admit countries that do not share their "ideas about the supreme values'

The Soviet stance may be due partly to pique. In their own opinion, as an eminent Soviet arms control expert, General Nikolai Chervov, stressed at the Royal have been replaced ledgement that, in economic crisis, the cafford to participate.

Institute of International Affairs last week, the Soviets have made a major concession to the West by softening their demands on SDI: instead of requiring that any arms control treaty outlaw all SDI-related research, they will now accept the compromise that such research be confined to the laboratory stage. Apart from some ironic questions about what, in the context of SDI, constitutes a laboratory, there has been virtually no Western response to this concession.

As for the alleged wish of the West to exclude the socialist countries from Eureka, the problem is a far wider one than a single programme. The whole idea of Eureka, as Bovin rightly noted, is to deal with leading edge technologies — lasers, computers, robots and biotechnology — precisely the fields affected by the Co-Com embargo on technology transfer. Furthermore, even if Eureka does include some programmes that would not come under Co-Com, the Socialist countries cited by Bovin have been remarkably quiet about their wish to participate.

The exception in the socialist bloc is East Germany whose leader, Erich Honecker, has publicly expressed some interest in participation, possibly within the framework of the existing intra-German trade arrangements, and, to a lesser extent, Yugoslavia (which technically ranks as a non-aligned country), where an initial interest now seems to have been replaced by a tacit acknowledgement that, in its state of endemic economic crisis, the country simply cannot afford to participate. Vera Rich

Patent law

Boost for Canadian drug research

Washington

AFTER a long and painful gestation, the Canadian government has finally given birth to proposals for changes in patent law. The amendments, actively sought by the pharmaceutical industry, will restore to patent holders exclusive rights to sales of patented drugs. In exchange, the government will require pharmaceutical companies to double their current research commitments in Canada.

Since 1969, Canada has had a unique law that allows generic drug manufacturers to obtain licences to produce patented drugs at any time. Once approved for sale by the health protection branch of the Department of Health and Welfare, generic manufacturers are in most cases obliged only to pay a 4 per cent royalty to the patent holder. Major, multi-national drug companies argue that this "compulsory licence" system discourages domestic investment and cuts sharply into profits. But for consumers, the benefits are obvious. A government report last year estimated that Canadians are saving \$220 million a year in drug costs under this arrangement.

Knowing that changing the compulsory licence system will provide political hay for the opposition, the government has several times delayed introduction of the amendments. But as the government has a 70-seat majority, the bill should pass into law unscathed. The government hopes to deflect some consumer criticism by establishing a new Drug Prices Review Board that can remove the protection from compulsory licences for companies whose prices rise too high.

Under the new laws, which will be presented to parliament in the fall but will apply from 27 June this year, companies will not be subject to compulsory licences for ten years. An additional ten years' protection from compulsory licences is offered to companies that manufacture a new drug in Canada. In exchange for such protection, the government has set targets for research expenditure by drug companies. Companies must increase research and development outlay to 8 per cent of sales by 1990, and 10 per cent by 1995. Research expenditure is now running at 5 per cent. Failure to comply with these targets could mean loss of protection from compulsory licences.

Other changes will bring Canada's patent laws in line with practices in most industrialized countries. Following the European model, patent applications will be open to public inspection 18 months after submission. Canada also plans to move away from the US system of awarding patents on a "first to invent" basis in favour of the European "first to file" ap-

proach. The government will also change patent terms from 17 to 20 years, and ratify the patent cooperation treaty.

While pharmaceutical industry trade groups have not yet formally endorsed the proposals, at least one pharmaceutical company is enthusiastic about them. Merck & Co. is moving immediately to complete plans for a Cdn\$20 million addition to its research complex in Montreal and expects to begin construction next year. By 1990, Merck estimates it will spend an additional \$100 million on research and development as well as creating 50 new scientific posts in Canada.

While victories are being won in Canada, the pharmaceutical industry has not been so fortunate in its dealings with the United States. For years, US drug companies have been seeking a change in the law to allow them to manufacture and export drugs that are not approved for sale in the United States.

Earlier this year an industry-approved bill reached the floor of the Senate, and the House was poised to consider similar legislation. But at the last moment, opponents added amendments so unpalatable to the industry that it withdrew its support for the legislation. The amendments would have placed tighter controls on export of infant formulas, and required additional notification procedures for exports of certain drugs.

Space vehicles

A short flight for Japan's shuttle

Tokyo

This is not the year for space flight. First it was the US Challenger, then Europe's Ariane, now Japan's shuttle has crashed to Earth seconds into its maiden flight. The craft's loss, however, is not a major setback — the shuttle was only a two-metre plastic model.

Last month, scientists from Japan's Institute of Space and Astronautical Sciences (ISAS), the space institute that earlier this year sent two probes to Halley's comet, test-flew a model of an orbital

re-entry vehicle. The white twin-finned shuttle was released at 1,000 m from a helicopter flying at 200 km per h 5 km off the Akita coast of Japan.

Equipped with a three-axis accelerometer, an angular velocity meter, a geomagnetic attitude sensor, an air-pressure sensor and a microprocessor, the model was supposed to be controlled from the ground and to relay information on altitude, attitude and velocity. But no sooner

was the shuttle set free than it looped the loop, turned into dive and 35 seconds later plunged headlong into the sea

A second test a few days later with a back-up model was more successful. After release, the shuttle remained airborne and glided steadily for 4.2 km while descending from 800 to 500 m. But it then veered left, failed to respond to correction signals from the ground, and 48 seconds later dived into the sea.

The ISAS team nevertheless considers the experiments a partial success. The telemeter system performed flawlessly and relayed data to Earth which show that the on-board roll stabilizer and yaw damper struggled valiantly to keep the shuttle on a steady course. But with no more models and a limited annual budget of only 100 million yen (£400,000), no further tests are planned this year.

The ISAS Working Group on Winged Vehicles, set up in 1982, is headed by Professor Makoto Nagatomo and has been carrying out computer simulation studies, wind tunnel tests and the present ballistics tests on Japan's shuttle of the future. Once a working model is made, the group hopes to attach a bigger version to a single-stage S-520 sounding rocket — but that would require an increase of two orders of magnitude in its budget, and funds are not yet forthcoming from the Ministry of Education, Science and Culture.

Beyond that, Nagatomo has outlined plans to develop a Highly Manoeuvrable Experimental Space (HIMES) Vehicle by incorporating a cryogenic engine into the shuttle. The HIMES vehicle could then be used as a self-contained re-usable sounding rocket or even as an orbital re-entry vehicle. But ISAS has no ambitions to build a manned shuttle — that is the preserve of the National Aerospace Laboratory and the National Space Development Agency.

David Swinbanks

West Germany

Terror against technology

Hamburg

KARL HEINZ Beckurts, a renowned physicist and one of the most important research managers in West Germany, was killed by terrorists of the Rote Armee Fraktion (RAF), in Munich on his way to work on 7 July. He and his driver, Eckhard Groppler, were victims of a 10-kg bomb, which was ignited electronically as they passed it in their car on their way from Beckurts' home in the Munich commuter village Strasslack to his Siemens office, where he worked as head of the department of research and technics, employing 36,000 workers.

Beckurts, who was born on 16 May 1930 in Rheydt, studied physics in Göttingen, first at the university and then at the Max-Planck-Institut for physics, where he finished his doctorate in 1956. Two years later he became head of the department for neutron physics and reactor technics at the Kernforschungszentrum in Karlsruhe. He moved to the Kernforschungszentrum in Jülich in 1970, and during his ten-year stay was responsible for its reorganization, introducing institutes for biotechnology and contact surface research. He then went to Siemens and became head of the research department.

Apart from his work there and his participation in the Grossforschungseinrichtungen, he taught in Karlsruhe and as an honorary professor in Bonn and Heidelberg. He is said to have been responsible for Siemens' leap into high-technology research.

Beckurts was also a keen supporter of the nuclear programme and it may be this that made him a target for the terrorists. He had fought for his conviction that, even after the Chernobyl disaster, a stable energy supply for West Germany must include nuclear power in the foreseeable future. Beckurts was also head of the Arbeitsgruppe Kernenergie of the Bund Deutscher Industrieller.

It is evident that in planning the killing the terrorisis took into account his support for puclear power as well as the new political situation in West Germany. There is now not only argument over quitting the nuclear programme, but also clashes between demonstrators and police in Brokdorf and Wackersdorf which prove the potential for violence on both sides and the readiness of a few to carry out criminal actions. RAF apparently seeks support from those who have already decided to abandon legal forms of action. A letter found near the site of the bombing "accused" Beckurts of having supported, apart from the nuclear programme, the US Strategic Defense Initiative (SDI) and the European research programme Eureka, described as programmes to further the "strategic reorganization of research and production". It is no surprise that a man like Beckurts was involved in consultation on Eureka and SDI, He had, however, committed himself to SDI, and, in spite of Siemens' participation, was not at all enthusiastic about Eureka.

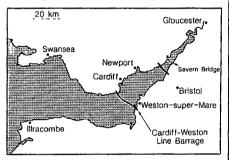

The assassination was apparently planned long in advance. Beckurts' name had been found on a list discovered in an apartment used by terrorists after the killing of Ernst Zimmermann, head of the

Motor- und Turbinen-Union, last year. Friedrich Zimmermann, Minister of the Interior, told the press that the Siemens manager had been warned. Safety measures will not, however, be tightened up. According to Zimmermann, there is no absolute protection against a remote-controlled bomb: not a very promising outlook for other endangered scientists. But laws regulating the right to demonstrate and the police law may well be tightened up. Political commentators say that this might have been a tactical aim of RAF, because more severe clashes could give them wider support or even new members from whom to recruit. Jürgen Neffe

Energy

Power from the Severn waters

THE world's largest tidal power-generation project came a step closer to realization last week with the decision of the UK Secretary of State for Energy to back a £5.5 million advanced feasibility programme. The decision was triggered by a new report showing that a 16-km barrage

across the Severn Estuary could be used to generate 14.4 TWh of electricity a year, six per cent of the nation's demand.

The idea of tapping the awesome energy of the Severn's tides — their 30 ft range puts them among the world's highest - has been around for a long time. In 1981, a committee under the chairmanship of Sir Hermann Bondi reported that a barrage was technically feasible. That provided enough encouragement for a more detailed study to be carried out by the Severn Tidal Power Group, a group of six major construction companies, with backing from the government. The report published last week says that the barrage, containing 192 turbine generators, could be built by the year 2000: six years of preconstruction development and seven years of construction, providing 44,000 jobs, would be needed. A further programme will now look in more detail at costs, performance and regional and environmental issues, as well as investigating a smaller tidal barrage scheme for the estuary of the River Mersey.

Two major issues have dominated discussion of the barrage scheme: the cost of the electricity it will generate in comparison with conventional power stations and

the effect it will have on the environment, particularly on the huge area of water behind the barrage.

Serious environmental problems are not foreseen by the report. Water will still flow into the Severn Estuary and it is believed that there would be little change in the salinity of the water or in the rate at which pollutants would move out to sea. But the tidal range behind the barrier would fall by half: although it would still be well within the range found elsewhere in Britain, there is no doubt there would be changes, which are not yet predictable, in the estuary's ecology. Ships using the Severn would be largely unaffected as locks will be provided in the barrage.

Calculating the costs of generated electricity has been more difficult as it depends on making projections into the next century. Electricity would be generated as the tide ebbed and rushed through the line of turbines. Pumping will add more energy: around high tide, when the level of the water either side of the barrier is the same, water can be pumped over the barrier. Later, when the tide has fallen, the extra water can be allowed to run out to give a net energy gain. The gain can be further increased if cheap rate electricity can be used for pumping and the generated electricity returned to the grid at peak rate times. One problem, of course, is that the time when electricity is generated is determined not by demand but by the tides. That, says the Severn Tidal Power Group, is not necessarily a problem: coal-fired stations can be kept on spinning reserve and brought up to full power as the tidal generators slow down.

Taking into account the need for this back-up, the tidally generated electricity seems likely to be marginally more expensive that nuclear-generated electricity but cheaper than coal-generated electricity. As it is unlikely that a large number of new nuclear power stations will be built this century, there should be room for tide power.

Alun Anderson

US education

Liberal colleges ask for more

EMPHASIZING their "significant and increasingly important contribution to America's scientific manpower pool", a group of fifty leading US liberal arts colleges say they will need to spend an additional \$1,000 million in the next decade to continue providing undergraduate training for future scientists. That conclusion appears in a preliminary draft report writ-

Earned doctorates in empirical and life sciences

Institution	Percentage
Cal Tech	37.5
Harvey Mudd*	37.2
MIT	18.6
Reed*	12.8
UC San Diego	10.8

Haverford*	7.5
Carnegie Mellon	6.4
Wabash*	6.4
Chicago	6.2

Percentage of graduates earning doctoral degrees comparing 50 liberal arts colleges with 20 top rated universities, Starred institutions are among 50 liberal arts colleges.

ten by Sam Carrier and David Davis-Van Atta of Oberlin College, presented last month at a conference on the future of science at liberal arts colleges.

The report is the second in a series assessing the role of small colleges as a training ground for scientists. The 1985 report showed that liberal arts colleges were relatively immune to a nationwide decline in the numbers of new students expressing an interest in majoring in a science discipline. Nearly 30 per cent of entering freshmen at the 50 liberal arts colleges included in the report said they were planning to major in science, compared with a national average of only 5 per cent. Women continue to represent a rising percentage of baccalaureate degrees in the sciences. More than 40 per cent of all undergraduate degrees for women in the 50 colleges were in the sciences.

The report attributes a large part of this strong showing to the close link between teaching and faculty research on the small campuses. Measures of academic distinction show graduates of the liberal arts colleges fare well when compared with graduates from larger universities. Carrier says the importance of liberal arts colleges is the quality of the students they produce as much as the quantity.

A problem for the smaller colleges is a stratification of faculty. At present their science faculties are overwhelmingly male (89 per cent), nearly all white (96 per cent), mostly in tenured positions (69 per cent) and relatively old (average age 44 years). The age distribution is skewed, with relatively few faculty younger than 30 or older than 55.

The 1986 report identifies the investments needed to maintain a strong position. Assuming a 1.1 per cent growth in faculty positions will be needed in the next decade, paying for these positions will cost an estimated \$369 million. To continue to attract a strong faculty, \$532 million will be needed to support faculty research, and an additional \$150 million for new laboratories and classrooms.

Appropriate ways of increasing investment in undergraduate science education have been a hot topic at the National

Science Foundation (NSF) recently. A National Science Board task committee chaired by Homer Neal (see Nature 320, 479; 1986) called on NSF to increase its support for undergraduate education to \$100 million annually. But NSF must still decide how to implement the Neal report recommendations, and must then win approval for new expenditures from the White House Office of Management and Budget and the Congress.

Carrier believes that the liberal arts colleges would fare well in competition for new NSF grants, but he expects a mix of federal, corporate and foundation support will be necessary to achieve financial goals. A third report to be produced by next summer will assess the issue of where the money should come from.

Joseph Palca

Chernobyl

Inquest continues on nuclear power

al improvements into the design of its nuclear power stations, according to Viktor Sidorenko, deputy chairman of the USSR State Committee for the Supervision of Safe Working Practices in the Nuclear Power Industry. But the type of improvement will be determined only after a detailed study has been made of the causes of the Chernobyl disaster.

In a statement released through the TASS news agency last week, Sidorenko said that his committee had been repeatedly asked, during the past few weeks, whether every reactor should have a dome-type containment building, which would prevent the emission of radioactive material into the external environment. Before Chernobyl, the Soviet stance had been that such containment buildings were unnecessary, and were merely a way for capitalist constructors to increase their profits. Sidorenko, however, took a slightly different line: that containment buildings are simply an alternative approach to safety, and that the Soviet system of modular "strong boxes", as used at Chernobyl, is a valid equivalent. It would be difficult to say at this stage, Sidorenko stated, whether a containment building would have reduced the scale of the Chernobyl emission.

Whether the two approaches are truly equivalent is a moot point. As a recent open letter to the International Atomic Energy Agency (IAEA) from an unofficial team of Polish scientists stressed, Soviet reactors have only two levels of containment, not as in the West, three. The more cautious purchasers of Soviet VVER reactors — Finns, Hungarians and Poles - have therefore insisted on a Western-style containment building being incorporated into the design.

Certainly the "modular strong-box"

THE Soviet Union is to introduce structur- 1.; approach failed to work for the RBMK reactor at Chernobyl, although, as Boris Semenov, deputy chairman of the USSR State Committee for Nuclear Energy, said in an interview with the Moscow Literaturnaya Gazeta in June, the design was intended to be sufficient to stop the leakage of radioactive material from the worst possible accident that could be foreseen: an instantaneous transverse rupture of the pressure header of the main circulation pumps.

One of the tasks of the government commission set up immediately after the accident is to determine and report on its cause or causes. Its other, and even more pressing duty, is to "eliminate the consequences" of the disaster. Since this is proving an extremely complex task, the report, which since the end of May has been promised "shortly", is not yet complete. (The arduous nature of the twofold task has, so far, worn out at least four, and possibly five, commission chairmen, all deputy premiers of the USSR.) Even without the official findings, and in spite of reports of faulty construction at Chernobyl, which appeared in the Ukrainian press before the accident, at least one Soviet official is quite sure that neither the design nor the construction of the Chernobyl plant was to blame.

Two days after Sidorenko's statement to TASS, Aleksei Makhukhin, First Deputy Minister of Power and Electrification, told the other official Soviet news agency, Novosti, that the accident seems to have been due to "a coincidence of several highly improbable and hence unforeseeable failures". Nevertheless, he admitted, although neither design nor construction was at fault, additional measures would be introduced to ensure greater safety of nuclear power engineer-Vera Rich

-CORRESPONDENCE-

A threat to medical progress

SIR—There have in recent years been several examples of a trend that has serious scientific and public importance, and in particular is liable to inhibit the development of medicine.

Any medical or surgical intervention carries, as is accepted, some degree of risk. Before devices or drugs are cleared for public use, they are subjected to close scrutiny and extended trials, and are released only if the risks are found to be acceptably small in relation to the much more substantial benefits. For example, it is accepted that the use of an intra-uterine device involves some slight increase in the risk of pelvic infection, but substantially less than the risks resulting from pregnancy, and it is equally accepted that all drugs carry some risk of undesired sideeffects.

However careful and extensive the trials may be, the release of a device or drug to the public provides data on a very much larger scale; this relationship is inevitable and unavoidable. In due course, further risks may come to light, usually those which are so small that they could not have been statistically significant in the original trials.

What is then liable to happen is that the manufacturer is subjected to lawsuits by people who have nothing to lose, and in particular clients of lawyers in those countries that permit contingency fees. These cases are tried and assessed by judges and juries who are not in general scientifically trained or knowledgeable, and who are unlikely to understand statistics or statistical causality. It is then probable that one or more of these cases will succeed, and it can afterwards be said that "it has been established by a court" that the substance or device is harmful.

The manufacturer is then on the horns of a dilemma. If it does not fight the lawsuits then it loses immediately. If it does fight them it may be put to enormous costs even if it wins, and by resisting the claims it is almost certain to attract hostile publicity, in particular media attention in which it is assumed and reiterated, without evidence, that what has been supplied is unquestionably harmful. The problem is so serious that once anything is even alleged against a supplier of a drug or a medical device, there may be little option than for the supplier to go into liquidation.

If this trend continues, it may well become commercially impossible for companies to develop anything new in medicine, and this would have serious public implications.

Of course some drug companies and other large firms have not been blameless, just as others have displayed a commendably responsible attitude. The problem is lawsuits and media emotionalism is almost entirely undiscriminating between those that have behaved well and those that have behaved badly. False sympathies are aroused by the media representing the problem as the little man or woman up against the commercial giant, but it needs to be remembered that it is the large company, rather than the retailer or physician, that is sued because it is only against a large corporation that large damages can be won, amounting in some recent cases to as much as £1 million.

Every sympathy and help is indeed due to someone damaged, in any circumstances, by medical intervention, but indiscriminate treasure-hunt suits do not fulfil this function and they confer a disbenefit on everybody who might need medical help in the future. The courts in this country have generally taken a responsible stand (and been castigated for it) by suppressing reports relating to a case sub judice; and when the report is eventually released, it may prove to be not evidence but only hearsay and unsupported assertion. Further legislative adjustment does however seem to be necessary, above all to strengthen discrimination in the assessment of alleged blame.

Monkeyed about

Sir-Tim Beardsley's News item "Monkey business: Bolivia asks for animals back" (Nature 319, 610; 1986) mentions squirrel monkeys and owl monkeys from Bolivia. The scientific names for both species are misspelled. For squirrel monkeys the correct spelling would have been Saimiri sciureus boliviensis, not "Saimiri scioureous boliviensis". Further, the appropriate nomenclature for Bolivian squirrel monkeys would have been Saimiri boliviensis boliviensis\.

For owl monkeys, the correct spelling would have been Aotus trivirgatus, not "Actus trivirgatusson". Further, the correct nomenclature would have been Aotus azarae. According to Hershkovitz², virtually all the owl monkeys in Bolivia should belong to one of two subspecies of Aotus azarae. Aotus exhibits substantial between-population chromosomal variation, and it is clear that it should not be regarded as a monotypic species (as has often been the case in the biomedical research community).

There is a clear need for primates and other animals used in biomedical and bethat the combination of contingency-fee | havioural research to be accurately identi- | Strand, London WC2R 2LS, UK

fied. For imported primates, specific sites of origin should be included in import documents and animal records. Too often scientists do not correctly identify their animal subjects, even in reports published in the best journals. Appropriate identification of primates should be a minimum requirement for their use and importation.

I urge all scientists who use primates to make a special effort to identify the animals they use, including geographic origin, and correctly to report this information in all published materials. For bibliographic assistance, scientists should make use of the services of the Primate Information Center at University of Washington.

J. ERWIN

American Journal of Primatology, PO Box 65481, Washington, DC 20035-5481, USA

Hershkovitz, P. Am. J. Primatol. 6, 257–312 (1984).
 Hershkovitz, P. Am. J. Primatol. 4, 209–243 (1983).

Tim Beardsley replies: The names were copied faithfully from the US Fish and Wildlife Service's import documents; there is no universally recognized taxonomy of squirrel and owl monkeys.

Soviet computers

SIR-Vera Rich reports skilfully on the planned changes in the administration of Soviet higher education (Nature 321, 716; 1986). Quite apart from the fact that one shudders a little whenever the Central Committee (or even someone like Sir Keith Joseph) announces that "we have plans for you", the situation in Soviet science is actually pretty grim for those who have to put up with it (even when they have all the privileges that come with the high status of an "Academician").

For example, at a recent meeting of the Academy of Sciences in Moscow, a very eminent scientist complained in public that not only was he short of computing power, which put him two or three years behind his American opposite number, but he gained a distinct impression that there were influential people around in Soviet science who did not think computers were essential. As a result he had to resort to "unusual ways" of acquiring his computer facilities (one imagines, either by smuggling them out of Western countries, or using the telephone to communicate with a computer in the United States).

The fact is that Soviet science is run by an establishment that makes our own University Grants Committee and Science and Engineering Research Council look like a collective of enterprising young men.

S.CHOMET

Department of Physics, King's College London (KOC), University of London,

Test ban made more respectable

A new study suggests that even the smallest nuclear explosions cannot be successfully hidden in holes beneath the ground, which makes a test-ban treaty a better proposition.

WHETHER or not there is eventually a comprehensive ban on nuclear tests, it will never be possible for politicians and others to claim that the academic community has failed to give the matter the attention it deserves. So much should be clear from the long account which occupies the first 71 pages of the current issue of Reviews of Geophysics, published by the American Geophysical Union, of the argument by which J.F. Evernden and two colleagues have been able to show that even attempts to hide underground explosions of nuclear weapons by conducting them in underground cavities cannot be successful (24, 143; 1986).

The question whether nuclear explosions might be concealed from the prying seismometers of invigilators first became a public issue in the 1950s, in the years preceding the abortive negotiations of a fully comprehensive test ban. In the event, the three governments in negotiation of the question, the Soviet Union, the United Kingdom and the United States, settled instead for a ban on all but underground tests, partly at least because of the belief that sizeable underground explosions might be effectively concealed by "decoupling" them from the surrounding medium. People were set to work ingeniously devising paper schemes for building spherical cavities in salt mines by solution mining and other methods. There was talk of muffling the seismic noise generated by explosions by factors of 50 or even 100. In the more recently aborted negotiation of a comprehensive test ban, in 1979, the three negotiating powers seem to have agreed to set aside the difficulty of concealment by decoupling, but the question has more recently been given a new lease of life and would no doubt be a stumblingblock again if serious negotiations on a comprehensive test ban were under way.

Not surprisingly, the question has an intrinsic as well as forensic interest. What really happens to the seismic signal of an underground explosion carried out in a cavity of some kind? Evernden is at the US Geological Survey at Menlo Park in California; the fellow authors of his latest contributions to the literature of the test ban are C.B. Archambeau (University of Colorado) and E. Cranswick (US Geological Survey), both at Boulder, Colorado.

The conclusion is heartening. According to Evernden *et al.*, it should now be possible to detect underground explosions in, say, the Soviet Union yielding explo-

sive energy equivalent to 1 kilotonne of conventional explosive even when these are fully decoupled from the surrounding rock. This, the authors say, could be accomplished by means of 15 monitoring stations outside the Soviet Union and by a network of 25 automatic seismic stations within the territory of the Soviet Union if they were so disposed as to make the most efficient use of the data gathered. The conclusion is heartening because, in the most recently aborted set of negotiations on the subject, the two major powers had agreed that each would provide house room for exactly 10 such stations.

How has this cheering result been obtained? Those who read the article by Evernden et al., as Evernden's earlier work on the same subject, will be struck by the way the argument is founded uncontentiously on empirical data. The starting point, for example, is a widely accepted formula (due to J.A. Sharpe and first published in 1942) describing the displacement field caused by an explosion in a supposedly homogeneous elastic material as a function of distance and of the frequency of the signal.

The physics of the process is well understood but none the less interesting for that reason. There is no doubt that an explosion in a cavity can in principle muffle the seismic signals from an underground explosion, partly because of the energy absorbed by the compression of the surrounding medium (air) and partly because of the sheer size of the cavity, which may imply that the pressure of the expanding explosive wave may be less, by the time that reaches the walls of the cavity, than that required to stimulate shock-wave propagation into the rock. And the result of that is that the wave from a decoupled explosion expands outwards, when it reaches the surrounding rock, even less efficiently than will the wave from a welltamped explosion.

It is good to be reminded by the article of Evernden et al. that the US authorities have in their time been obliging in their willingness to allow these predictions to be verified experimentally. Indeed, the authors make good use of the experiment conducted beneath the Nevada desert in the 1960s, when one nuclear explosion was used to make a cavity and another, smaller and later, was used to test the then current understanding of decoupling.

The essence of the argument now published turns on the dependence of dis-

placement at a distance from an explosion of any kind, decoupled or not, on the frequency at which the seismic signals are measured. Simply, the amplitude of the seismic signals is roughly a constant up to a certain value and then appears inversely proportional to the square of the frequency. Moreover, this "corner frequency" is itself a function of the magnitude of the explosion.

The practical consideration is that while the reduction of the seismic amplitude caused by decoupling in the low-frequency range may be very large, amounting to a factor of as much as 100, the disparity in the high-frequency range may be much less, a factor of 10 or so. What Evernden and his associates now propose is that the detection of decoupled explosions will be most efficient in the highfrequency region. Although the magnitude of the seismic displacements is itself reduced by the inverse-square variation of displacement with frequency, modern instruments could cope with that. But the reduced signal strength at higher frequencies explains why it is necessary to increase the number within the Soviet Union from the 10 talked of in 1979 to 25 now.

This latest contribution to the literature of the detection of decoupled explosions will surely not be the last on the subject. Indeed, Evernden and his colleagues raise hares fit for half a dozen investigations. There is, it seems, a possibility that decoupled explosions may be distinguished from well-tamped explosions, raising the possibility that attempted violations of a comprehensive test ban might be detectable. The limits of the sensitivity of detection arise, it turns out, from the confusion caused by wind-driven micro-seismic activity; the network of 25 internal stations is so chosen as to make use of the efficient propagation of high-frequency signals through the shelf structures of mainland Asia. Perhaps the most serious drawback in a system for detecting explosions as sensitively as that now proposed is that quite modest explosions of conventional chemicals would be detectable, raising the awkward possibility that the proposals for on-site inspection of suspicious places, one of the unprecedented provisions of the most recent draft treaty, would too often raise demands for inspection when none was called for. But that is not a serious obstacle to an agreement between governments prepared to take modest John Maddox

Origin of life

RNA and hot-water springs

from E.G. Nisbet

THE discovery that RNA molecules can extrude introns which can then act as enzymes (refs 1,2; see the recent News and Views article' by Frank Westheimer) makes the notion that life began from RNA very attractive. The most likely site for the inorganic construction of an RNA chain, which would have occurred in the Archaean, is in a hydrothermal system. Only in such a setting would the necessary basic components (CH4, NH3 and phosphates^{1,5}) be freely available. Suitable pH (fluctuating around 8) and temperatures around 40°C are characteristic of hydrothermal systems on land. Furthermore, altered lavas in the zeolite metamorphic facies, which are rich in zeolites, clays and heavy metal sulphides, would provide catalytic surfaces, pores and molecular sieves6 in which RNA molecules could be assembled and contained. If the RNA could then replicate in such a setting with the aid of ribozymes and without proteins, the chance of creating life becomes not impossible but merely wildly unlikely.

Models of self-replication

A self-replicating von Neumann machine needs a list of instructions (DNA and RNA in life); a set of organs (proteins) to help in the replication of the list; and a container which protects a local degree of order so that the components can find each other. In some models the container is dispensed with by the assumption that the oceans were a 'soup' of organic molecules. This is most improbable, as the Archaean oceans were probably rapidly processed through lavas in submarine hydrothermal systems at temperatures of several hundred degrees.

In the modern Earth, a volume of sea water equivalent to the entire oceanic volume passes through the mid-ocean ridge hydrothermal systems in about 10⁷ years⁸, whereas in the early Archaean this circulation time was probably 10° years or less ".". Unless the production rate of organic molecules in the ocean and atmosphere was high, the soup was probably clear and with chemistry not greatly different from today. Furthermore, NH, and CH, would not be present in any significant amounts as they would have had very short lifetimes in the atmosphere". It therefore seems unlikely that life began in the open ocean.

In other models12, the nucleic acid 'list' is dispensed with and proteins are called on to replicate themselves, but in this case it is difficult to see how the mechanism of replication could have the necessary specificity. The subsequent evolution of

nucleic acids would have to be from information in polyamino acids, which is not according to the central dogma. In an alternative model13, the list is based on clay minerals which can replicate themselves and do not need a protective container; but it is not clear how a daughter could detach itself from the parent and assume an independent existence.

In contrast to these interesting but complex models, the discovery that RNA can splice out a length of itself, which can then act as an enzyme¹⁻³, suggests a much simpler path to life. RNA is not only a list, but can also help⁷ to replicate the list. What is needed to complete the model is the third component, a suitable container or environment in which an RNA molecule could be assembled and could detach daughter ribozymes, yet still retain access to them.

A shallow-level hydrothermal system is the most likely setting in which all the necessary components could have been assembled to create a polynucleotide. First, only in hydrothermal systems could significant partial pressures of CH, and NH, exist in the Archaean Earth.

Second, hydrothermal systems carry large quantities of phosphorus, which has been dissolved out of basalt glass'. Typical mid-ocean ridge basalts contain 0.1-0.2 per cent P₂O₅, virtually all of which is lost to solution on the passage of hydrothermal fluids5. In the earliest Archaean the flux released by this route would have been much greater than today, and would have dominated the global supply of phosphorus, especially in the absence of a large sedimentary inventory on the continents.

The third reason for favouring a hydrothermal setting is the availability of inorganic catalysts. Altered basalts and pillow breccia consist of a porous fabric which includes a complex microcrystalline aggregate of zeolites, clay minerals and heavy metal sulphides, as well as albite, carbonates and relict primary phases. Enormous volumes of water flow through such altered rocks, with varying pH, chemical content and temperature, depending on the activity of the driving volcanic heat source and the local geology. Zeolite minerals can act as molecular sieves6, allowing the passage of small molecules while retaining large molecules. They also have remarkable and highly specific catalytic properties similar to enzymes¹⁴; the catalytic effects of clay minerals¹⁵⁻¹⁷ are well known. The abundant pores and cavities in altered basalt would provide an extraordinary assortment of inorganic containers lined with

zeolite molecular sieves, ranging in size from the zeolite cage⁶ (about 11 Å) to cavities several centimetres long.

If a molecule of RNA capable of selfreplication formed in this setting it would be in a fabric of altered rock, probably in a pore surrounded by a molecular sieve of zeolite. The pH of some Icelandic hydrothermal systems fluctuates in the range 7.5-8 (in contrast to submarine systems which are acid); such systems also have large regions at temperatures around 40°C; and the concentrations of Mg²⁺ and Cl ions in the hydrothermal systems would favour replication of RNA.

The RNA world

In a recent News and Views article18. Walter Gilbert postulated that the first stage of evolution was in an RNA world. In this model world, life consisted of selfreplicating RNA molecules and used recombination and mutation to explore new functions and adapt to new niches. Eventually a wide range of enzymic activities would develop by using RNA co-factors. Later, RNA would begin to bind and synthesize proteins which would eventually take over the enzymic role. A hydrothermal system would be ideal for providing the amino-acid components in this process¹⁹. In such a world, replicating systems in pores in altered rock close to the water-rock interface could pass from pore to pore in the altered lava, by chance as hydrothermal systems varied. They would eventually colonize their habitat to the extent of available resources. Any molecule which could replicate more faithfully by isolating itself from the random catalytic effects of zeolites and clays (once so useful, by now a source of error) would be strongly favoured by natural selection 10. A system which learned to surround itself with a bag of lipids would be more successful at reproduction and would be pre-adapted to life in the open ocean.

Cosmology

What makes nearby galactic clusters all move as one?

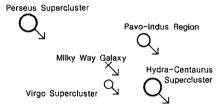

from Joseph Silk

No matter how hard cosmologists try, they have been unable to come up with a simple scenario that simultaneously explains both galaxy formation and the large-scale frothy structure of the galaxy distribution. One class of models, characterized by cold dark matter in the form of weakly interacting elementary particles, does well at explaining small-scale structures, but stumbles at the hurdle of the clustering of galaxy clusters. Another class, characterized by hot dark matter in the form of massive neutrinos or dark baryons such as burnt-out stars or black holes, shows promise of matching the large-scale structure, but at the cost of failing to form galaxies early enough in the Universe. The one point of consensus is the existence of pervasive dark matter, although the lack of any evidence as to its nature has opened the floodgates of speculation. More exotic avenues are being explored, the most promising of which involves cosmic strings, relics from the very early Universe which can act as seeds for the growth of structure on both small and large scales (see Hogan, C. Nature News and Views 320, 572; 1986).

It is premature to tell whether strings will be the cosmic panacea. But no sooner have cosmologists recovered from the momentous discovery of the bubble-like structure of the galaxy distribution on scales of tens of megaparsecs (Mpc) (see my News and Views article, Nature 320, 12; 1986), a remarkable new result is being announced. That our Local Group of galaxies is whizzing through space at a speed of about 600 km s⁻¹ towards a direction not far from the southern constellation of Centaurus is well known. This motion shows up as an unambiguous dipole anistropy in the cosmic microwave background (CMB) radiation, seen as a slight heating of the radiation in the direction in which we are moving and as a slight cooling in the reverse direction. Recently it has been reported that our Local Group is not a lone wanderer in intergalactic space, but that galaxies throughout a vast region of about 100 Mpc in extent are companions in its headlong rush. Evidence for this alarmingly coherent large-scale flow has been independently found by two groups.

David Burstein (Arizona State University) and co-workers from six other institutions spanning the globe from Pasadena to Herstmonceux (R. Davies, A. Dressler, S. Faber, D. Lynden-Bell, R. Terlevich & G. Wegner) have presented data on some 400 elliptical galaxies evenly distributed

on the sky. The measured parameters (central velocity dispersions, effective radii and total magnitudes) defined a sufficiently good correlation that enable distances to be inferred once distance-independent parameters (such as velocity dispersion and total magnitude) have been measured. This survey, the results of which were presented at a recent meeting in Hawaii and reported in the News and Views article by Richard Bond and Sidney van der Bergh (Nature 320, 489; 1986), shows that there is a bulk motion of about 700 km s⁻¹ of essentially all galaxies within $60 h^{-1}$ Mpc of the Local Group (h = 1 if the Hubble constant is 100 km s⁻¹ Mpc⁻¹, or $h = \frac{1}{2}$ if the Hubble constant is half of this value). The direction of this motion is towards galactic longitude $l = 299^{\circ}$ and latitude $\vec{b} = +1^{\circ}$ and within 20° from the apex of the dipole motion which yields the Local Group motion relative to the CMB.

350,000,000 LIGHT YEARS

A traveller at rest with respect to the microwave background radiation looking down on the superclusters would see them moving with about the same velocity in about the same direction. The arrows represent, to scale, the velocities the traveller would see.

(Graphic by David Burstein.)

Another group, working at Imperial College London (Collins, C., Joseph, R. & Robertson, N. Nature 320, 506; 1986) obtained infrared photometry for an allsky sample of the class of galaxies termed Sc at a mean distance of 50 h^{-1} Mpc. Again, by adopting the known correlations between their derived distancedependent parameter (infrared luminosity) and distance-independent parameters (infrared colour or central velocity dispersion) either absolute distances or Hubble velocities can be inferred once the correlations are calibrated. Comparison of Hubble velocity with the observed recession velocity for about 45 galaxies led Collins and colleagues to infer a bulk streaming velocity of 970 (± 300) km s⁻¹ in a direction towards $l = 305^{\circ}$, $b = 47^{\circ}$ that, within their large quoted uncertainty, is consistent with Burstein et al.'s result.

To many astronomers, this is a case of déjà vu. The large-scale motion amounts to a confirmation of the Rubin-Ford effect, a motion of the Local Group relative to a shell of Sc galaxies at $\sim 50 h^{-1}$ Mpc that, following its initial discovery in 1976 by Vera Rubin and Kent Ford, has generally been disbelieved until now. After all. the inferred direction of motion was nearly orthogonal to the apex of the Local Group motion relative to the CMB. This neglect may have been unjustified. Indeed, the first indication of a large-scale bulk motion came with the confirmation by several groups that the Local Group is falling towards the Virgo cluster at ~ 250 km s⁻¹ and in a direction some 45° away from the apex of its CMB motion. This means that, in the reference frame of the CMB, the entire Virgo Supercluster, including the Local Group at a distance of some $10 h^{-1}$ Mpc from Virgo, is moving at ~ 400 km s⁻¹ in the direction of Hydra-Centaurus

The new data on ellipticals tell us that clusters in Hydra - Centaurus in the south. and in Perseus and Pisces in the north. separated by a distance of $\sim 60 h^{-1} \text{Mpc}$. are all sharing a common motion with Virgo, whose amplitude may be as large as 700 km s⁻¹. We are all moving towards a region behind the Hydra-Centaurus clusters. According to Burstein et al., there is an additional component of random motion of $\sim 300 \text{ km s}^{-1}$ for individual clusters superimposed on the bulk flow. Finally, of course, the CMB must represent the ultimate local rest frame. It is reassuring that A. Yahil, D. Walker and M. Rowan-Robinson have confirmed in a study of IRAS galaxies that at a depth of $\sim 200 h^{-1}$ Mpc, the galaxies are indeed at rest with respect to the CMB (Astrophys. J. Lett. 301, L1; 1986). (Similar results were reported last summer at the Princeton dark matter symposium (in the press) by A. Meiksen and M. Davis.)

Reconciling these new data with existing models of large-scale structure will be a difficult task as no model predicts such large velocities. If the interpretation of the data holds up then something must be pulling us; exactly what is not clear. Indeed, it has been argued by N. Vittorio, R. Juszkiewicz and M. Davis (Nature in the press) that confirmation of the large-scale bulk motion will invalidate all hot or cold dark matter models that rely on inflationgenerated random phase perturbations of a Friedmann cosmology. Less attractive models may work: these include low-density Friedmann cosmologies containing either hot or cold dark matter, together with primordial seeds that have triggered early galaxy formation. The seeds might be cosmic strings, as proposed by T. Kibble, A. Vilenkin and Ya B. Zel'dovich (see Hogan, C. Nature News and Views **320**, 572; 1986), or rare objects that have injected sufficient energy via supernova

explosions to explosively amplify the perturbed mass scale up to galactic dimensions, as discussed by J. Ostriker & L. Cowie (Astrophys. J. Lett. 243, 127; 1981) and S. Ikeuchi (Publ. astr. Soc. Japan 33, 211; 1981).

The one source of solace is that the large-scale bulk motion does seem to be a likely consequence of the existence of the Hubble bubbles. These apparent voids, on scales up to $50\ h^{-1}$ Mpc, could have been generated by the large-scale flows which would evidently be present in a hot dark matter-dominated universe. Of course, these flows must have maintained considerable coherence to preserve the well-defined bubble surfaces on which the galaxies are found. If this were the case, the bubble interiors should be genuinely devoid of matter.

There is an alternative, needless to say,

offered by advocates of cold dark matter namely that the voids are illusory, simply reflecting the large-scale inhomogeneity of the luminous matter, concentrated into great clusters and into ridges of galaxies, from the relatively smooth dark matter distribution. Such a situation could arise if only the highest peaks in the primordial fluctuation spectrum managed to form galaxies. But however this biasing arose, one consequence is inevitable: the large-scale flows must turn out to be an artefact of observational error. Astronomers are now rushing to verify the reality of the large-scale flows: their confirmation promises to mark a turning point in cosmology.

Biochemistry

New role for transfer RNA

from Robert Haselkorn

BIOCHEMISTRY is conservative, and as a rule the same biochemical step is carried out in pretty much the same way throughout the kingdoms, microbes and man alike. It is unusual, therefore, that this rule is broken by a basic step in the biosynthesis of haem and chlorophyll. These molecules are both modified forms of a conjugated ring molecule called a tetra pyrrole nucleus, made by the condensation of several molecules of the amino acid *δ*-amino-levulinic acid. But it turns out that δ-amino-levulinic acid is made in very different ways in the cells of animals and plants. As Schön et al. report in this issue (Nature 322, 281; 1986), a glutamyl transfer RNA molecule participates in this pathway in chloroplasts.

Labelled acetate and glycine were shown 40 years ago (Shemin, D. & Rittenberg, D. J. biol. Chem. 166, 621; 1946) to be the exclusive precursors of the carbon atoms of haem in mammals and, later, in photosynthetic bacteria. Subsequent work showed that acetate entered the tricarboxylić acid cycle and the key step in the synthesis of hacm is the condensation of the cycle intermediate succinyl CoA, with glycine, to make δ -amino-levulinic acid. This is then transported from the mitochondria to the cytoplasm where subsequent steps in porphyrin biosynthesis occur. When the radioactive tracer experiments were eventually repeated using plant extracts (Beale, S.I., Gough, S.P.& Granick, S. Proc. natn. Acad. Sci. U.S.A. 72, 2719; 1975), it was found that the carbon atoms of δ-amino-levulinic acid were not derived from acetate and glycine but from α -ketoglutarate via glutamate.

During the past decade it was shown

that glutamate is reduced to glutamic semialdehyde and the latter transaminated to produce δ-amino-levulinic acid in chloroplast extracts. Various mechanisms were proposed for the glutamate reduction, some involving phosphorylated intermediates. Participation of RNA in the conversion of glutamate to δ -amino-levulinic acid was first indicated by work at the Carlsberg Laboratory in Copenhagen and at the University of Iowa (Huang, D.-D. et al. Science 225, 1482; 1984). Evidence that the RNA is a glutamyl-tRNA was obtained independently by W.-Y. Wang in Iowa, S.I. Beale at Brown University and the group of D. Söll at Yale University. In this issue, Söll's group reports that the intermediate in barley chloroplasts is one of three isoaccepting glutamyl-tRNAs. This tRNA, which has the unusual modified base 5methylaminomethyl-2-thiouridine in the first anticodon position, is the only one that functions as a substrate for the reduction to glutamic-semialdehyde. Whether this glutamyl-tRNA also functions in protein synthesis is not yet known. The tRNA is encoded in chloroplast DNA.

The two alternative paths to δ-amino-levulinic acid arose, I believe, separately in the heterotrophic and photosynthetic bacteria on the one hand and in cyanobacteria on the other. Heterotrophic bacteria are the evolutionary precursors of mammalian mitochondria while cyanobacteria are the ancestors of chloroplasts. Succinyl CoA and glycine are available raw materials in heterotrophic bacteria, but succinyl CoA is in short supply in most cyanobacteria, which lack the complete tricarboxylic acid cycle. Reduction of an

organic acid to an aldehyde proceeds nicely via an ester intermediate; what better source of glutamate ester than glutamyl-tRNA, already on hand for protein synthesis? To avoid competition for the same intermediate, the glutamyl-tRNA used to make δ-amino-levulinic acid should be modified to prevent its use in protein synthesis, but whether that is actually the case remains to be determined, as noted above.

The failure to observe incorporation of glycine into porphyrins in plants and most green algae suggests that the chloroplast pathway provides δ-amino-levulinic acid for all biosynthesis in plants. What is wrong with plant mitochondria? Where did they come from? Plant mitochondrial DNA is much larger than its mammalian counterpart, replete with direct and inverted repeats that recombine frequently to generate an array of circular molecules. Some plant mitochondrial DNA sequences are homologous to chloroplast DNA; at least one such sequence originated in the chloroplast because it encodes a major chloroplast enzyme. Other plant mitochondrial DNA sequences have nuclear homologues, suggesting a history of rather promiscuous exchange of genetic material between organelles in the evolution of plants. With δ -amino-levulinic acid supplied by chloroplasts, selection for the mitochondrial pathway in plants would be relaxed and the relevant genes could have been lost in the shuffle.

An exception to the general proposal that plants lack the glycine-succinyl CoA condensation pathway is known. The alga Euglena, evolutionarily bizarre in other respects, has been shown to contain both pathways (Weinstein, J. & Belae, S.I. J. biol. Chem. 258, 6799; 1983). However, so far the green algae Chorella and Chlamydomonas, as well as cyanobacteria, are believed to contain only the plant pathway to δ -amino-levulinic acid. A number of the outstanding questions raised by Schön et al. could be approached conveniently by the isolation and characterization of mutants, for which Chlamydomonas and Anacystis appear to be the organisms of choice. Useful in this connection could be a compound called gabaculine (5-amino-1,3-cyclohexadienyl acid) that probably inhibits the transaminase that converts glutamic semialdehyde to δ -amino-levulinic (Gardner, G. & Gorton, H.L. Plant Physiol. 77, 540; 1985). A collection of mutants resistant to gabaculine ought to include a few that affect the tRNA and the tRNA ligase as well as the transaminase. Examination of the δ -amino-levulinic acid pathway in fungi would also be rewarding from an evolutionary viewpoint.

Robert Haselkorn is in the Department of Molecular Genetics and Cell Biology, University of Chicago, Chicago, Illinois 60637, USA.

Cell biology

An unfolding story of protein translocation

from James E. Rothman and Roger D. Kornberg

THE general rule of co-translational protein secretion and membrane insertion is faced with a growing number of exceptions. Many cases are now known in which translation can be completed before membrane translocation. The difficult enough issue of how a nascent polypeptide traverses a membrane and folds up on the other side has, therefore, given way to the more general and seemingly impossible problem of how a fully folded, soluble protein can pass the permeability barrier of a lipid bilayer. Fundamental insight into this problem comes from the ingenious experiment of Eilers and Schatz, described on page 228 of this issue1, which implies that proteins unfold as they are imported into mitochondria. The existence of enzymes that unfold proteins has been indicated in other contexts; such activities may have broad significance.

Newly made proteins potentially can cross several translocational-competent membranes in the cell. For proteins targeted for import into mitochondria and the endoplasmic reticulum, the specificity is usually determined by the nature of the amino-acid sequence at the extreme amino terminus. Mitochondrial precursors have a leader peptide or signal sequence that is usually charged and hydrophilic. Proteins targeted to the endoplasmic reticulum, on the other hand, have a signal peptide that is mostly hydrophobic in character.

To test whether a protein unfolds as it crosses the mitochondrial membrane, Eilers and Schatz produced a fusion protein consisting of a mitochondrial signal peptide linked to the amino terminus of a well-characterized enzyme that is not normally translocated across any membrane, dihydrofolate reductase. They could then ask whether the translocation of dihydrofolate reductase into mitochondria (measured in a now standard type of cell-free system) is affected by a small molecule (the inhibitor, methotrexate) that binds tightly to the active site of the enzyme. If dihydrofolate reductase crosses the membrane in its folded form, then the binding of methotrexate should be without effect on transport (the methotrexate would simply be transported as well). But if the enzyme must be unfolded in order to cross, then methotrexate should profoundly inhibit uptake, by stabilizing the folded structure of enzyme.

The results of Eilers and Schatz show that import of dihydrofolate reductase (but not other mitochondrial precursors)

is virtually abolished by methotrexate. Moreover, the K_i for inhibition of import is the same as the binding constant of methotrexate to the active site of dihydrofolate reductase. Direct evidence that methotrexate binding stabilizes the compact, folded form of the enzyme comes from proteolytic digestion studies. Only the amino-terminal signal peptide and not the remainder of the fusion protein is accessible to digestion, whereas both parts of the molecule are degraded in the absence of ligand binding.

The bipartite nature of the dihvdrofolate reductase fusion protein, with an exposed amino-terminal signal peptide and compact core, fits nicely with the finding by Schleyer and Neupert2 that transport into mitochondria is at least a two-step process. First the amino-terminal signal and some additional sequence traverses the membrane; then the rest of the chain follows. Schleyer and Neupert trapped protein precursors between steps, in the act of translocation, by using low temperatures, both in vitro and in vivo. In the two cases examined (the beta subunit of F, ATPase and cytochrome c_i), the polypeptide chain is caught with its amino terminus penetrating the matrix space (shown by cleavage of its signal peptide) but with much of its mass still on the outside of the mitochondrion where it is susceptible to external proteolytic attack. Only the first step of import requires energy, derived from the mitochondrial membrane potential, because the remainder of the process occurs when the temperature is raised in the presence of energy poisons. The energy that drives protein unfolding must be introduced in the first step, even though complete unfolding may only occur later.

A similar multi-stage process involving protein unfolding may operate during protein translocation across endoplasmic reticulum and across bacterial plasma membranes. It was recognized several years ago3.4 that protein transport across bacterial membranes can occur posttranslationally, as in mitochondria. Only recently, however (as discussed in the recent News and Views article⁵ by Schatz), has it become apparent that translocation across the endoplasmic reticulum membrane can also occur post-translationally, although in at least some cases the completed chain must still be attached to the ribosome6. This suggests that all forms of translocation may have common mechanistic features⁵, possibly including an unfolding step.

Previously, all the evidence had suggested that transport across endoplasmic reticulum membranes was unique in being coupled to protein synthesis, implying that already folded chains are unable to cross. It now appears that when a precursor is unable to cross the endoplasmic reticulum post-translationally it is the fault of the precursor and not of the translocation machinery. Such a precursor simply does not put its best foot forward. apparently folding in such a way as to obscure its signal sequence. As would be expected, post-translational import of proteins by the endoplasmic reticulum requires energy, although in the form of a nucleoside triphosphate, rather than a membrane potential. One wonders whether energy is also used here for an initial step in which the signal sequence traverses the membrane.

Is the machinery that drives protein unfolding limited to membranes? If such a machine were free in the cytoplasm and operated under the same principles, it could unfold selected sets of proteins with selectivity being based on the appropriate 'signal' on the protein (analogous to the endoplasmic reticulum and mitochondrial signal sequences). For example, if a proteolytic activity were built into an unfolding machine, then selected proteins would be degraded as they were unfolded in the cytoplasm. Proteolysis would be ATP-dependent because of the need for energy in unfolding, and it would be limited to substrate proteins unfolded within the machine. Indeed, the ATP-dependent protease from Escherichia coli that is responsible for the degradation of partially denatured proteins seems to couple unfolding to proteolysis in such a fashion.

This remarkable enzyme, described by Goldberg and colleagues ', degrades a polypeptide chain into small, acid-soluble peptides, starting from one end and finishing off the chain it is degrading before it starts another. This processive degradation requires sustained ATP hydrolysis which, Goldberg and co-workers suggest. rapid translocation of the enzyme along its polypeptide substrate Were such an enzyme mounted in a membrane (deprived of its protease activity), it would translocate a polypeptide substrate past itself and across the membrane. The ATP-dependent protease from E. coli thus seems to represent the first known protein translocator.

The power of unfolding enzymes could also be harnessed for constructive purposes. Such enzymes could even catalyse the fundamental process of protein folding. Although this process is generally viewed as spontaneous, because isolated polypeptides can re-fold efficiently, artificial manoeuvres such as the gradual removal of a denaturing agent are often required. Wrongly folded structures

otherwise form and persist. Misfolded proteins in a cell might be recognized by virtue of the chain they expose and then be actively unfolded to allow the folding process to repeat itself rapidly until a compact structure of minimum energy is achieved. Such catalysis of folding by unfolding enzymes would set a minimum stability for a correctly folded structure.

The situation would be analogous to the action of helix-destabilizing proteins such as E. coli recA^{10,11}, and single-strand binding proteins¹² in catalysing the reassociation of DNA single strands. These proteins presumably bind to the sugarphosphate backbone of DNA and destroy wrongly paired duplexes of limited size that would otherwise persist for some time, allowing the strands to reassociate repeatedly until a stable structure, paired in the correct register along its entire length, is achieved. Proteins that act in a similar fashion to facilitate protein folding might recognize and bind to the backbone of a polypeptide chain. Such proteins would act in concert with other factors, such as an enzyme discovered long ago, which facilitates thiol-disulphide interchange during protein folding until the correct (most stable) arrangement of disulphide bonds is achieved¹³⁻¹⁵.

The exciting possibility emerges that cells have a set of unfolding enzymes. When they span membranes such as those of the mitochondrion or rough endoplasmic reticulum and have the appropriate signal-recognition machinery to provide the specificity for initial entry of the protein substrate, they catalyse translocation and unfolding. When a protease activity is built into the unfolding enzyme, selected proteins can be degraded as they are unfolded. One can even imagine an unfolding enzyme lacking proteolytic activity that still recognizes incorrectly folded proteins. Such an enzyme would correct the errors by allowing misfolded polypeptide chains a chance to try again. Is it possible that the rapid acquisition of a three-dimensional structure, one of the few processes in cells that seems to occur without the aid of enzymes, may in fact receive help? This unfolding story is far from wrapped up.

Neurotransmission

Are there two functional classes of glutamate receptors?

from Charles F. Stevens

A RECENT article in Nature1 and two that appear on page 263 and 265 of this issue2.3, help to clear up some mysteries about excitatory synaptic transmission in the brain. Neurones that respond to the excitatory neurotransmitter glutamate generally possess at least two distinct classes of receptors, classified by the artificial agonists that excite them, into NMDA (for N-methy-D-aspartate) and non-NMDA types. Under normal recording conditions the NMDA type has rarely seemed to operate. The two articles in this issue show that the NMDA receptor is, indeed, used and define some conditions that determine its use, whereas the earlier article shows why two distinct classes of neuronal glutamate receptors may be useful.

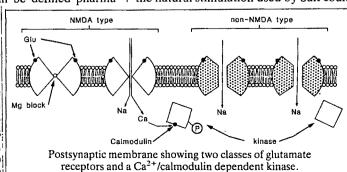

Acidic amino acids, especially glutamate, are to the brain what acetylcholine is to the neuromuscular junction. That is, where acetylcholine is used for excitatory synaptic transmission between nerve and muscle, glutamate is used at brain excitatory synapses. It is likely to be that more than half the neurones found in the brain use glutamate as their neurotransmitter.

At least three distinct classes of glutamate receptors can be defined pharma-

cologically. One class responds to NMDA, whereas the other classes respond to kainate and quisqualate. evidence Some suggests that the kainate and quisqualate receptors may be separate, but these two receptor types! are often classed together and often only two main classes of receptors - NMDA and non-NMDA — are distinguished. Amino-phosphonovalerate (APV) is a specific blocker for the NMDA receptor class but general glutamate receptor blockers that work on all classes are also available. Many neurones have high densities of binding sites for NMDA and are strongly excited when NMDA is applied directly to their surface. Although this excitation is effectively blocked by small doses of APV, this antagonist generally has little effect on excitatory transmission produced by stimulating presynaptic axons. Such excitation, however, is well blocked by broad-spectrum glutamate receptor antagonists. Therefore excitatory synaptic transmission must be normally mediated by the non-NMDA receptor class but what, then, is the function of NMDA class of receptors?

Salt² has investigated the contribution of NMDA receptors to synaptic transmission on the thalamus and has found, as is the case of other synapses, that the blocker APV has no effect on the baseline discharge of thalamic neurones and does not alter the response of the thalamic neurones to electrical stimulation of the excitatory pathways that project there. NMDA receptors would thus seem not to be involved in synaptic transmission in the thalamus. However, when natural stimuli are used, for example puffs of air instead of electric shocks, APV almost completely blocks the response of these same thalamic neurones. In other words, NMDA receptors appear to be used when the stimulation is natural but not when afferent pathways are stimulated synchronously with electric shocks.

A clue to how this paradoxical result could arise is provided by the observation of Herron et al.3. Although the conditions of their experiments differ from those of Salt, they find, using only electrical stimulation, that the intensity and pattern of stimulation can favour the participation of NMDA receptors in the response of a neurone. Their findings can be explained in several different ways, one of which is that NMDA receptors respond preferentially to low concentrations of glutamate and non-NMDA receptors respond to higher concentrations. By the same explanation, the natural stimulation used by Salt could

perhaps give rise to lower agonist concentrations than would synchronous stimulation, thereby favouring the use of NMDA receptors in one case and non-NMDA receptors in the other. Although further experiments will be needed to sort out the precise mechanisms involved, NMDA receptors are clearly there to be used.

But why are two classes of receptors required? One important difference between the two receptor classes is that the efficacy of synaptic transmission using NMDA receptors (but not the non-NMDA type) depends strongly on the voltage of the postsynaptic cell: if the membrane potential of a neurone is quite negative, NMDA applied directly has no effect whereas NMDA is quite effective in causing excitation (depolarization) if the neurone is already excited (depolarized). This property is, as far as we know, unique to NMDA receptors and arises through an interesting mechanism^{4.5}. NMDA always causes channels to open, but at negative voltages the channels are immediately blocked by physiological concentrations of magnesium ions whereas at more positive voltages the magnesium ions are driven out of the pore and the NMDA channel can excite the neurone by permitting sodium ions to flow in.

The paper by McDermott et al. demonstrates another important distinction between NMDA receptor channels and their non-NMDA counterparts: activation of NMDA receptors permits not only sodium but also calcium ions to flow into the cell and to produce significant increases in

the local calcium concentration.

One important consequence of this calcium flux in at least some neurones has been suggested following an observation first made by Saitoh and Schwartz⁶ and recently confirmed and extended by Miller and Kennedy⁷. A kinase regulated by calcium, known to be present in the postsynaptic membrane, appears clustered at many excitatory synapses, so that glutamate action on NMDA-type receptors would produce a calcium influx and consequently activate this kinase. The recent studies reveal that, when sufficiently stimulated by calcium, this kinase phosphorylates itself, and the phosphorylated enzyme then remains active even when calcium concentrations return to resting low levels. Activation of NMDA-type channels then can activate a kinase and switch the metabolic state of the postsynaptic region. Precisely which proteins the kinase phosphorylates, what function they have and whether this effect is a basis for learning and memory as is widely suspected, are questions whose answers should not be long in coming.

Ocean Drilling Program

Palaeoclimatic linkage between high and low latitudes

from the Leg 108 shipboard scientific party*

One of the major questions in palaeoceanography concerns the linkage between the polar components of the climate system (ice sheets, sea ice and polar oceans) and the low-latitude ocean-atmosphere components (surface ocean, upwelling regions, wind circulation and land climate). Potential linkages between high and low latitudes have been proposed for timescales ranging from the early Cenozoic12 to the late Pleistocene^{3,4}. The central question is whether the two portions of the system are independent or interdependent, and if interdependent, to what degree and through which linkages?

The answer to these questions is important for the current debate on the relative contributions of ice-volume variations and ocean-temperature changes to the δ¹⁸O record, particularly in low-latitude planktonic foraminifers. It is also important in understanding long-term aridityhumidity cycles on the African continent, which seem to be driven by orbital insolation variations5, but which may also depend on evaporation from equatorial surface waters. In addition, the transfer of carbon from the surface to the deep ocean in productive upwelling regions may provide global climatic feedback via atmospheric CO, levels.

Between 21 February and 17 April, Leg 108 of the Ocean Drilling Program (ODP) cored more than 3,800 m of sediment at 12 sites in the eastern equatorial Atlantic (Fig. 1). At the coarse resolution achieved with our shipboard analyses, the initial results suggest a broad-scale late Neogene linkage between the polar and equatorial responses, but further shore-based analyses at the resolution of orbital periods (20,000-100,000 yr) will be necessary to determine the kind of link.

Results from three sites (657, 658 and)

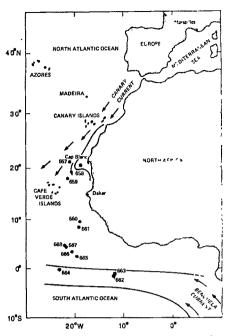

Fig. 1 Sites cored by Leg 108. Arrows, major current systems; dotted areas, regions of strong Plio-Pleistocene upwelling and divergence

659) in and outside the upwelling system driven by Northern Hemisphere trade winds along the north-west African margin suggest a substantial intensification of coastal upwelling since 3 million years (Myr) ago. A progressive intensification during the past 3-2.5 Myr also emerges from analyses of sediment at three sites along the south equatorial divergence (662, 663 and 664). In both locations, these conclusions are based on increases in the content of opaline silica (diatoms) and organic carbon in layers increasingly rich in terrigenous silt and clay from the late Pliocene to the Pleistocene. These indicators become more abundant in successively deeper Plio-Pleistocene CaCO, minima, probably at orbital rhythms (Fig. 2). Our conclusions are further supported by changes in the frequency of cool-indicator nannotossils. planktonic foraminifers and diatoms. In addition to local divergence and upwelling driven by northern and southern trade winds, some of the response in each region may also represent increased equatorwards advection of cool water by stronger eastern boundary currents in each hemisphere (Fig. 1).

The level of resolution of the shipboard

analytical signals (approximately 50,000 yr) does not allow us to distinguish between whether these trends developed slowly over the past 3 Myr or whether they developed with abrupt step-like changes in amplitude. Regardless, a clear firstorder correlation exists between this equatorial trend and that seen in polar climates. Northern Hemisphere ice sheets first attained sufficient size to initiate ice rafting in the subpolar North Atlantic at 2.5 Myr (refs 7,8). Moderate-scale variations in ice-sheet size during the past 2.47 Myr then culminated in the large-amplitude 100,000-yr cycles during the past 650,000 yr (refs 9,10). The changes in equatorial upwelling/divergence show about the same late Pliocene onset and Plio-Pleistocene intensification (Fig. 2).

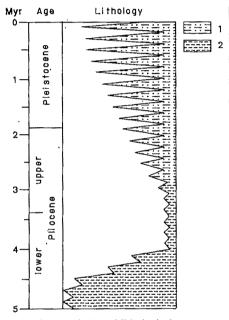

Fig. 2 Schematic log of lithological sequences obtained in and near north-west African margin upwelling area (sites 657, 658 and 659) and equatorial divergence area (sites 662, 663 and 664). CaCO, cycles increase in amplitude progressively from 3-2.5 Myr until the present, with non-carbonate lithology consisting mainly of silty clay with opaline (diatom) silica and minor amounts of organic carbon. I, Silty clay with diatoms; 2, red clay.

In addition to the north polar and equatorial changes, there is also evidence of northwards expansion of the Antarctic Circumpolar Current and the Antarctic polar front at and after 2.7-2.6 Myr (ref. 11). The fact that all three regions experienced nearly simultaneous changes complicates direct cause-and-effect interpretations. Similar first-order synchroneity of responses in polar regions and equatorial oceans has also been noted for the late Miocene 12-14

The exact polar-equatorial linkage thus remains unknown. Eventually, the question will best be answered by orbital-scale analysis of the long Leg 108 sequences using the numerical approaches pioneered by Project SPECMAP10. At this level of

analysis, the more exact criteria for defining climatic interdependence (analysis of orbital rhythms, phasing and coherence) will narrow the range of explanations.

There are already some suggestions of linkages from orbital-scale studies of conventional piston cores. Late Pleistocene surface-ocean coolings along the north-west African margin appear to vary with the size of Northern Hemisphere ice sheets4.15. In contrast, the equatorial surface waters have a predominant 23,000-vr signal in the late Pleistocene; not only is the dominance of this rhythm different from the distribution of orbital power in the ice sheets, but the equatorial seasurface temperature response leads ice volume by several thousand years¹⁶. Because the geographical equator lies south of the thermal equator in a region of Southern Hemisphere influence, the equatorial surface ocean may be forced from high southern latitudes on orbital timescales. Thus, the two primary upwelling/divergence regions in the tropical/ subtropical eastern Atlantic may be driven from opposite polar regions.

Fine-scale analyses will be aided by new correlation techniques introduced on Leg 108. Previous Deep Sea Drilling Project (DSDP) and ODP palaeoceanographic legs, despite coring two offset holes with the hydraulic piston cores at some sites, have had difficulty obtaining continuous sections; disturbed cores and incomplete recovery of some sections create gaps in the sediment sequence and thus in the climatic record. Only DSDP Leg 94 succeeded in verifying continuity of section in detail (tens of centimetres) at sea by tracking CaCO, layering in core photographs and then spot-coring any gaps.

ODP Leg 108 introduced a more sophisticated strategy that should be applicable to future palaeoceanographic legs in regions of large lithological variability. We measured two signals (P-wave velocity and magnetic susceptibility) at intervals of 3 cm or less on unsplit cores, which allowed correlation of the records at the offset holes to within a few centimetres. As a result, laboratory analyses of the various upwelling/divergence or tradewind signals are provided with a 'road map' showing precisely which sections to analyse from the offset holes to obtain a complete record of each site. In addition, P-wave and magnetic susceptibility signals contain orbital-scale rhythms and may prove as useful as some of the more conventional palaeoclimatic indicators.

We found evidence of one major Neogene change in palaeo-deep-water circulation: preservation of CaCO, was poor before 4.6-3.8 Myr, with red clay below 4,000 and dissolved calcareous sedimens above (Fig. 2). After that time, preservation markedly improved, with CaCO, preserved to well below 4,000 and less dissolution of the shallower calcareous sections. This change appears to represent the culmination of a cyclical long-term late Neogene trend towards improving CaCO, preservation that began in the late Miocene. An accompanying increase in sedimentation rates was more narrowly bracketed at several sites between 4.6 and 3.8 Myr. This change in the CaCO, compensation depth is the major equatorial Atlantic deep-water shift of the Plio-Pleistocene.

Thyrotrophin-releasing hormone

New applications in the clinic

from Ewan C. Griffiths

As a result of research reported at a recent meeting*, it seems likely that thyrotrophin-releasing hormone (TRH) and its analogues are about to attract interest as novel therapeutic agents in various neurological disorders. TRH, the tripeptide L-pyroglutamyl-L-histidyl-L-prolineamide (Burgess, R. et al. Nature 226, 321; 1970), acts as a hypothalamic hormone in stimulating the release of thyrotrophin (and other hormones) from the anterior pit-

*Therapeutic uses of TRH, Santa Barbara, California, 6-8

uitary. More than 70 per cent of the total brain content of TRH however, is found outside the hypothalamus and several initial studies suggested that it might be useful clinically as an antidepressant. But none of the analogues produced proved useful, so interest in the hormone declined.

One particular line of research that has re-awakened interest in TRH now is the demonstration that TRH can reverse induced states of shock and spinal injury (J.W. Holaday, Washington DC; A.I. Faden, San Francisco; S. Amir, Rehovot). In endotoxic, anaphylactic, lipoxygenase-induced and leukotriene-induced shock, TRH has proved a remarkable agent in increasing survival and reversing depressed cardiovascular and respiratory function. In spinal cord trauma, this neuropeptide was particularly effective, though not in dog and gerbil models of brain ischaemia. In a rat model of cerebral ischaemia (Latham et al. Regul. Peptides 13, 80; 1985), two TRH analogues given intraventricularly have been dramatically effective: RX 77368 (pGlu-His-[3,3'-dimethyl] ProNH₃) and CG3509 (orotyl-His-ProNH₃).

One area of clinical relevance for TRH is in motor neurone disease or amyotrophic lateral sclerosis. There are improvements in muscle tone and function after intravenous TRH treatment in some, but not all, patients with motor neurone disease and other types of spasticity (W.K. Engel, Los Angeles; B. Brooks, Madison). Other preliminary findings on the improvement of muscular functions in motor neurone disease used intrathecal administration (T. Munsat, Boston). These three studies suffer from short duration of action of TRH which has a half-life of 4 min or less. To overcome this, R. Guiloff (Westminister Hospital, London) has undertaken a clinical trial in patients with RX 77368, an analogue that binds well to TRH receptors and, compared with other analogues, is extremely stable and potent (my own observations). The patients treated with RX 77368 had significant improvements in speech, respiratory function, tongue movements and swallowing and decreased spasticity. There was also a marked increase in force of muscle contraction and in motoneurone activity.

How does TRH and its analogues work in motor neurone disease? Some clues have come from the work of Valerie Askansas (Los Angeles) who finds that motoneurones grown in culture in the presence of TRH show increases in choline acetyltransferase activity and neurite outgrowth, so perhaps the hormone is a neurotrophic agent. Further evidence for a neurotrophic effect has come to light through the reported reversal by TRH of neuronal damage caused by the substance P antagonist spantide (Freedman, J. et al. Expl Brain Res. 62, 175; 1986), and the stimulation of myelin lipid synthesis in chick neural cultures (Kanamoto, Y. et al. Brain Res. 371, 201; 1986). In patients with motor neurone disease, there is a loss of TRH and TRH receptors in the spinal cord (laminae II and ÎX). TRH is known to excite a-motoneurone activity and may act at several central and peripheral neuronal sites to cause the improvements observed in motor neurone disease.

Further potential applications arise from the variety of central nervous system actions attributed to TRH. In an animal model of Alzheimer's disease (neuronal damage induced by AF 64A, a nitrogen I mustard derivative of choline), another TRH analogue MK771 (L-pyro-2-aminoadipyl-His-thiazolidine-4-carboxamide) was reported by A. Horita to reverse the decrease in choline acetyltransferase activity. Because Alzheimer's disease is believed to involve a cholinergic deficit, perhaps TRH and its analogues could be used to reverse this deficiency. In view of the antiopioid actions of TRH (except in prolactin release and analgesia), it might be useful in treating narcolepsy and, through its analeptic effects, in the reversal of anaesthesia. Similarly, there is no really satisfactory therapy for either stroke or spinal injury and although there may be a time-limit on the effectiveness of the hormone, this is another possible use.

Such a list of previously untreatable

conditions has not gone unnoticed by the pharmaceutical companies, and besides motor neurone disease, clinical trials are being planned or are already under way with TRH and its analogues in spinal injury. Perhaps there is greater scope for the more stable analogues with enhanced duration of action, and choice of the best one from a long list of analogues now available can be assisted by both biological studies and theoretical prediction of conformation (Ward, D.J. et al. Regul Peptides 13, 73; 1985). After being thought of only as an ineffective antidepressant and a means of testing anterior pituitary function, TRH is making a comeback.

Biological chemistry

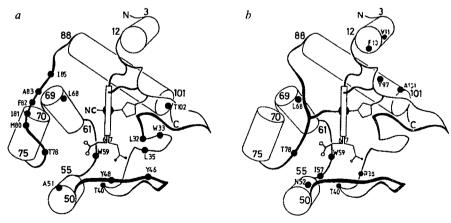

Long-range electron transfer

from R.J.P. Williams and D. Concar

THE basis of many biological processes, including many fundamental steps of energy transduction in membranes, depends on long-range (10-20 Å) electron transfer. The postulation of these electron hops, based on observations of complex biological pathways, was necessary as soon as it was realized some twenty years ago that the metal centres of electrontransfer proteins are embedded in folds some 5-10 Å from the surfaces of the proteins. That such processes were possible was then demonstrated by theoretical and solid-state studies. But the recent results of S. Isied and colleagues, reported elsewhere in this issue (Bechtold, R. et al. *Nature* **322**, 286; 1986), apparently throw

much of our subsequent knowledge of these processes into question.

The concept of long-range electron-hop reactions originally met with scepticism from inorganic chemists, who analysed reactions in small well-defined complexes in solution. Recently, several groups of biochemists and inorganic chemists (or bio-inorganic chemists) decided therefore that a thorough attack on the problem was necessary to show the constraints on through-protein electron hopping in solution systems. The protein cytochrome c is the major experimental object. Different approaches to the problem include protein to protein electron transfer; free small molecule (ferrocyanide) to protein

a, The fold of cytochrome c. Black spots, residues known to be affected by redox state changes. The larger effects are towards the bottom and left corner. The major change Met 80 - ALa 85 on substitution at the iron (in b) by CN*. Other residues known to be affected are shown as black spots. Grosser effects are towards the bottom left-hand corner. These diagrams are of cytochrome c from tuna. The site labelled W33 in a is equivalent to His 33 in horse cytochrome c, the species studied by Isied and co-workers. His 33 is the bound site of electron-transfer ruthennum reagents and is in a conformationally stable region. Lys 13 and 72 are on the front protrucing edge of the protein by the haem where reagents such as $[Fe(CN)_0]^1$ bind

transfer; and bound (crosslinked) small molecules (usually ruthenium complexes) to protein electron transfer. The last method, in avoiding the need to determine independently the binding constants and sites of the reagents, is particularly attractive, and it is this method that Isied and collaborators have used to produce their disturbing results.

Before discussing the results of Isied's group in detail, we will briefly describe the ribbon structure of cytochrome c (see figure). X-ray diffraction studies of crystals of the protein and nuclear magnetic resonance studies of the protein in solution leave no doubt that the ribbon structure undergoes only a small change from the Fe(11) to the Fe(111) state. Nuclear magnetic resonance additionally provides a dynamic map of fluctuations and their energetics in the protein and has also been used to analyse the structural change and energetics associated with substitution at the iron (see figure). This is a first-order groove-opening reaction dependent on the breaking of the Fe(111)-methionine 80 bond and some small protein rearrangement involving a concerted movement of the section of the protein mainly under the haem. As a result of these studies, the following position was firmly established before the report of Isied's group.

- (1) Electron transfer is a reversible phenomenon, which is axiomatic for self-exchange. Provided differences in redox potential are taken into account for forward and back reactions, there is no doubt about reversibility of electron transfer to or from free anions (ferrocyanide), bound cations (ruthenium derivatives) or other proteins (cytochromes b). There were no known gated bimolecular reactions involving cytochrome c.
- (2) A small activation energy is associated with electron transfer for all three types of reaction with some small protein rearrangement (see figure), but electron transfer could not involve a step as energetic as the Fe-Met bond break or ring flips that is, electron transfer has an activation energy of 10-20 kJ and not of the order of 50-100 kJ.
- (3) There is an understandable distance dependence for electron-hop transfer with a rather higher transmission coefficient than expected from theory. This helps to allow long-range (10–15 Å) electron transfer at rates as fast as is commonly found in protein-to-protein electron hopping. Protein-small molecule (free or bound) electron transfer is usually somewhat slower and complicated by solvent relaxation energies, that is, the same type of relaxation, but larger, as that of the small conformation change in the metal protein on redox change, where the protein is the effective solvent.
- (4) Electron transfer at these low redox potentials has little dependence on the chemical (amino acid) between the

Dame Honor Fell FRS (1900–1986)

DAME Honor Fell FRS, who died on 22 April, was the pioneer of the technique of organ culture by which small organs or organ rudiments can be successfully grown in vitro. In such cultures the various tissue components and their spatial relationship and function are preserved so that the explanted organ closely resembles the parent tissue in vivo. In her hands the method proved particularly suitable for the study of developmental processes in fetal organ rudiments but has since been adopted and is still used for the cultivation of adult tissues.

Using this method she made a major contribution in the elucidation of the processes involved in skeletal development. She showed that both avian and murine limb bone rudiments have a remarkable capacity for self-differentiation and will grow and differentiate in the same manner in vitro as the organs in situ. She further showed that both growth and differentiation could be modified by extrinsic factors, such as vitamins and hormones.

An important example of this modification is the influence of vitamin A on the differentiation of cartilage and ectoderm. She showed that vitamin A added to the culture medium of avian ectoderm modified the direction of epithelial differentiation. The vitamin suppresses normal keratinization and induces mucus-secreting ciliated epithelium instead associated with an increase of sulphur uptake by the metaplastic cells. In embryonic cartilage the vitamin causes a severe breakdown of the matrix with a loss of metachromasia.

This finding formed an important link with her more recent investigations into

the mechanisms involved in joint damage in arthritis. To simulate the rheumatoid pannus she grew pig articular cartilage in association with synovium and showed that the synovium, either in direct contact with the cartilage or in medium conditioned by synovial cells, has, like vitamin A, a deleterious effect on the cartilage ground substance, leading to a loss of proteoglycans and collagen, and of metachromasia.

Together with her colleagues at the Strangeways Research Laboratory, Cambridge, United Kingdom, she traced this effect to a factor secreted by the synovial cells, now identified as the polypeptide catabolin/IL1. Her finding constituted a major advance in the understanding of joint destruction in arthritis and forms the basis of much vigorously pursued international research in this field.

Honor Fell obtained her PhD in Zoology at Edinburgh University in 1923 and the same year joined Dr T.S.P. Strangeways at what was then the Cambridge Research Hospital. After his death in 1926 she became Director of the Laboratory now renamed Strangeways Research Laboratory in 1928, a post she held until 1970.

Under her directorship the small laboratory grew to a major institute of worldwide reputation. In the post-war years the laboratory became a focal point for visiting biologists from abroad whom she trained in *in vitro* methods and who came to rely on her advice, guidance and encouragement, which were unstintingly given. She was one of the most outstanding biologists of this century and her death means the end of an era in biomedical science.

Ilse Lasnitzki

centres, whereas at high potential aromatic groups can act as hopping stations.

The experiments of Isied and collaborators throw all of these conclusions into question. Their results seem to show that the electron-transfer rate, properly corrected for redox potential, can be dependent on the *direction* of electron transfer, that is, it is irreversible. This means that different micro-states are involved for the reaction Ru(II) to Fe(III) and Fe(II) to Ru(III) in cytochrome c. Unless there is a gross experimental error in the characterization of species (for example, in structure) this means that this electron transfer can be gated.

The authors offer explanations as to how this could come about and they refer to the conformational states of cytochrome c we have described above. It has to be admitted that some states, such as those involved in the flipping of certain aromatic rings and groove openings, do involve activation energies of up to 100 kJ per mole, but it is hard to see how these motions could have anything to do with the electron-transfer steps in only one

direction, especially as they are not involved in the other reactions described above. This is not to say that in some proteins, such as cytochrome P-450, electrontransfer reactions are not gated — in the case of P-450 they are gated by substrate binding. But in the very simple case under discussion we have a puzzle on our hands, in that one set of observations is completely out of line with all the others. Clearly the puzzle can be resolved only with a large series of measurements.

Given the importance of the observations of Isied and colleagues it is essential that at least one other group of inorganic chemists makes the same study independently. Until that is done we face the data with bewildered amazement, frankly hoping that they will go away. If they do not, we must re-examine a considerable part of our thinking about protein energy states and not just about electron transfer.

SCIENTIFIC CORRESPONDENCE

Visual observation of lightning propagation

Sir-Reliable scientific observers' have reported discerning direction of movement and propagation in long-duration horizontal lightning flashes. With measured velocities between $5.6 \times 10^{\circ}$ and 1.1× 10⁴ m s⁻¹ for horizontal flashes⁴, lightning approaches the upper threshold for detection of movement by the human eye.

During a nocturnal thunderstorm over Ann Arbor on 9 June 1985, we were able to observe and photograph cloud-to-air lightning that appeared to propagate so slowly that we were able visually to observe apparent movement. The photograph of one of these lightning flashes reproduced here neither supports nor contradicts the visual observation of propagation, since it represents a time exposure. Because this photograph shows only a large, widely branched lightning flash, we were prompted to review both the physics of the flash and the limitations of the human visual system to better understand what we perceived.

Even a long-duration lightning flash (≥ 0.4 s) is too brief to allow interpretation of the observation, since the duration of a perceptual experience is around 0.4 s for the dark-adapted visual system5, even following the briefest stimuli. The time frame is also too fast to allow the eve to track the flash; so what we must have observed was the temporal ordering of the flash.

A lightning flash usually consists of successive discharges (strokes) along the same channel, and channel sections have been observed to propagate with a mean

pause time of 0.06 s, with about four pause { times per horizontal channel. The fovea of the eve is able to determine temporal order perfectly with a pause of 0.3s between the onset of two targets. Thus the time frame of propagation of long-duration horizontal lightning flashes is more than adequate for the visual processing system to resolve temporal ordering. If the mean duration of such a flash is 0.43 s (ref. 4), the flicker rate of the flash would be around 17 Hz, well below the critical fusion frequency, but too fast for the individual strokes to be counted accurately'.

The initial visual stimulus of the lightning flash shown below was probably a single channel extending downwards from the base of the clouds. The image of the initial and subsequent channels would be renewed in the observer's visual system with each stroke of the flash, enhancing the perception of movement and propagation for the observer.

Controversial glycosaminoglycan conformations

Sir-The issue of the ring conformation of the α-L-idopyranuronate residue in dermatan sulphate, heparan sulphate and heparin — three important biological classes of glycosaminoglycans — was recently debated by Rees et al.1. At least for dermatan sulphate, the authors explained how a postulated conformational equilibrium of the iduronate residue between a prevalent 'C₄ and a minor 'C₁ chair form was compatible with experimental observations, including extreme susceptibility of dermatan sulphate to periodate oxidat-

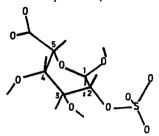

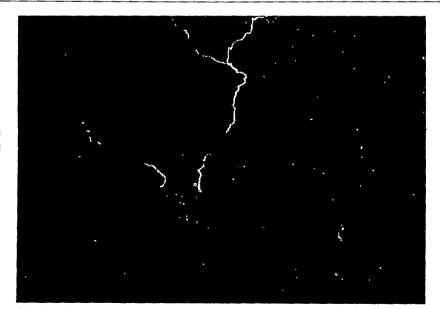

Fig. 1. The ²S₀ skew-boat conformation for the 2-O-sulpho α-L-iduronate residue.

ion. It was stated that "also possible are various distorted chairs and skew boats but these are not discussed here since their consideration would constitute a second order of analysis". This last statement prompts us to air our own views on this controversy

In a recent work², a detailed forcefield study of the conformational characteristics of methyl 4-O-methyl-2-Osulpho-α-L-idopyranosiduronate demonstrated that the ring may indeed adopt three nearly isoenergetic conformations ¹C₄, ⁴C₁ and the skew boat ²S₀. The vicinal coupling constants ${}^3J_{\rm ini}$ observed for heparin and various heparin oligosaccharides containing (I₂₅), the 2-sulphate iduronate residue⁴, were subsequently interpreted' in terms of conformeric coupling constants computed by using the Karplus-like equation proposed by Altona and colleagues' and the molecular geometry obtained from force-field calculations2. For heparin and synthetic oligosaccharide sequences contained in heparin, the I_{2s} residue shows considerable populations of only two conformations, ¹C₄ and ²S₀, the percentage of the skew boat ²S_a found (40 to 64%) being a function of the sequence. A similar analysis has been achieved for the non-sulphated α-Iiduronate residue in dermatan sulphate (D.R.F., A.P. and M.R., unpublished data). The vicinal coupling constants of the iduronate ring observed in dermatan sulphate were computed by means of Altona's relationship' relating the 'J_{int} to the dihedral angles H-C-C-H, which were obtained from force-field calculations on methyl α -L-idopyranosiduronate. iduronate residue in dermatan sulphate

Cloud-to-air discharge emanating from cloud base of about 2 km at 4:30 a.m. EDT on 9 June 1985 at Ann Arbor, Michigan, USA, photographed with a Chinon camera with a 58mm lens at f/1.8, with the shutter held open until after the flash ended, using Kodachrome ASA 25 35-mm slide film.

was shown to be in equilibrium between ${}^{1}C_{4}$ (58%) and ${}^{2}S_{0}$ (42%).

We have also analysed data for various naturals or synthetic (J.-C.J., T. Chiba and P.S., unpublished data) glycosides of non-sulphated L-iduronate. A considerable population of the two chair conformers ${}^{1}C_{4}$ and ${}^{4}C_{1}$ has been found, in this particular case where the α -L-iduronate residue is unsubstituted at position 4. The main difference between the two sets of coupling constants corresponding to the presence of either ${}^{2}S_{0}$ or ${}^{4}C_{1}$ lies in the value of $J_{3,4}$ which in the former case remains small, even when $J_{3,4}$ is quite large.

Finally, 4-unsubstituted glycosides of 2-O-sulpho- α -L-idopyranuronate exist mainly (> 90%) in the $^{1}C_{4}$ conformation as also evidenced by the observation of longrange coupling constants ($J_{1,3}$ and $J_{2,4}$ from 0.5 to 1 Hz) in synthetic as well as disaccharides and oligosaccharides (B. Perly and M.P., unpublished data) derived from heparin.

The participation in the conformer equilibrium of α -L-iduronate residue located *inside* a glycosaminoglycan chain of the well-defined 2 2 S_n skew boat, which results in a quasi-equatorial orientation of its hydroxyl groups, is an equally plausible explanation for the observed susceptibility to periodate oxidation of unsulphated L-iduronate residue in glycosaminoglycans.

Moreover, the unique conformational flexibility of α -L-iduronate residues may explain some important binding and related biological properties of dermatan sulphate, heparan sulphate and heparin.

Ulcerative rhabdovirus in fish in South-East Asia

SIR-Annual outbreaks of a severe ulcerative disease with high mortalities of wild and pond cultured freshwater fish have been reported throughout South-East Asia since 1980'. The condition is characterized by the appearance of large, deep ulcers on the body and/or head with varying degrees of destruction of the underlying tissues. Many species are considered to be susceptible but the striped snakehead (Ophicephalus striatus), one of the economically most important species, has perhaps suffered the most severe losses. Pollution of the natural waterways and fish ponds with insecticides and herbicides, particularly paraquat, is believed by some workers to be the major cause of disease whereas others consider the nature, distribution and pattern of spread of the outbreaks to be more consistent with an infective condition.

Between October 1985 and February 1986, wild and pond cultured fish showing varying degrees of skin ulceration were obtained from widely dispersed locations in Thailand and Burma and subjected to virological examination. Portions of liver, kidney and spleen were removed from affected fish, homogenized in Hanks' balanced salt solution, clarified by low-speed centrifugation and the supernatants

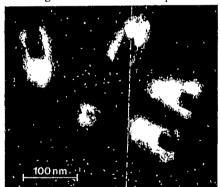

Fig. 1 Rhabdovirus particles from second passage on snakehead cells.

decontaminated by filtration through 450-nm membrane filters. Monolayer cultures of a cell line derived from snakehead fry were prepared using Leibovitz L-15 medium supplemented with 10% fetal calf serum as growth medium and 1 ml aliquots of filtered supernatant added to 25cm cultures. After allowing absorption for 1h at room temperature the cultures were overlaid with 7 ml maintenance medium (L-15 + 2% serum) and incubated at 28°C. Cytopathic effects developed between 3 and 14 days post-inoculation. Cells

became granular, rounded up, detached from the monolayer and lysed. This progressed at varying rates over some days until virtual total destruction of the monolayer had occurred leaving only fine, granular debris in the culture medium. Aliquots of media were inoculated onto fresh snakehead cell cultures to confirm transmissibility of the effect.

Electron microscope examination of phosphotungstic acid stained pellets obtained following ultracentrifugation of cell culture fluids from passaged samples revealed bullet-shaped virus particles (Fig. 1). The overall dimensions of these typical rhabdoviruses were $120 \pm 10 \,\mathrm{nm} \times$ 80 ± 5 nm. Morphologically indistinguishable particles were recovered in cell culture from diseased snakeheads from the Bangkok region of central Thailand, Chiang Mai in northern Thailand, Udornthani in northern Thailand and snakehead and freshwater eel (Fluta alba) from the Rangoon area of Burma. The size of the particles corresponds closely with that of other recognized fish-pathogenic rhabdoviruses2-5, but further studies are required to determine the relationship of the ulcerative disease isolates to these pathogens.

Although a virus infection has always been recognized as the possible primary cause of disease and virus-like particles of varying morphology have been observed in the tissues of diseased fish, this is the first report of the isolation of a single virus type from more than one species of diseased fish in widely separated geographical areas. However, many diseases of fish cause clinical signs only in adverse environmental conditions and this ulcerative condition seems such a disease. The fact that outbreaks occur in Thailand only during the cooler months of the year suggests that a falling water temperature may be a prime stress factor in this region but other environmental conditions may be precipitating factors elsewhere. Overall we consider the balance of evidence to implicate the rhabdovirus as the likely primary causal agent of the disease.

Two Cambridge cultures

William Cooper

The Red and the Blue: Intelligence, Treason and the Universities. By Andrew Sinclair. Weidenfeld & Nicolson: 1986. Pp.179. £12.95. To be published in the United States by Little, Brown.

I THOUGHT I couldn't bear to read another book about Burgess, Maclean et al. — or even a book in which they appeared as characters. I'm allergic to spies. SNEAKS ALL, I call them; regarding the CIA, KGB and MI5 as having more in common with each other than they have with the rest of us. As for the sneaks themselves, some of them are so eaten up with the vanity of sneakery that they can't resist sneaking for both sides at once! Vain and trivial people. Were the CIA, KGB and MI5 disbanded tomorrow, the difference in our world ten years hence would be insignificant.

Burgess, Maclean, Philby and Blunt appear throughout as characters in Andrew Sinclair's The Red and the Blue, to which he gives the more explanatory subtitle, "Intelligence, Treason and the Universities". I found I could read the book with admiration and approval. The universities in question are chiefly Cambridge and the period covered begins with the First World War and ends in the present day; the central feature of that period in Cambridge being the glorious era of physical discovery in the Cavendish Laboratory, discovery in atomic and nuclear physics which had a revolutionary impact on world history. The glory was at its peak in the years around 1932 — just when Burgess, Maclean, Philby and Blunt embarked on their private pettifogging tricks that have so hypnotized the British popular press. Mr Sinclair, however, judges his perspective on the whole Cambridge scene with a combination of independence, accuracy and understanding. (He took a double first in History at Trinity College, Cambridge.) His interpretation owes much to the concept of "The Two Cultures", first publicized by C.P. Snow in 1959 — which is when Mr Sinclair graduated, so he only arrived on the scene in person ten years after the half-way mark in his story.

From the end of the First World War to the beginning of the second, the scientific culture is epitomized, obviously, by the Cavendish Laboratory — Rutherford, Chadwick, Blackett, Cockcroft, Rutherford's remarkable Russian protégé, Kapitsa, and others. Kapitsa founded a very influential open club, where scientists could publicly exchange information about their discoveries. The literary culture is epitomized by a secret society called The Apostles, "a self-electing élite of

those who considered themselves the brightest and best in contemporary literature and philosophy", its members drawn from the privileged classes, male and mostly from Eton, no scientists — Keynes, G.E. Moore, Wittgenstein, E.M. Forster, Bertrand Russell and others. They were given to passionate mutual admiration; devotion to the growth of private virtues (in natural reaction against the collective madness of the earlier war); personal liberation in pursuit of beauty, love and truth — and furthermore, pursuit of beautiful young men, known to them in its platonic form as The Higher Sodomy... oh dear! It is a truth universally unacknowledged that extremely clever people can be ineffably silly: high intelligence is not automatically bonded with commonsense. The Apostles had their Bloomsbury offshoot, known as the Bloomsberries: Lytton Strachey, Leonard and Virginia Woolf, Clive Bell and Vanessa Bell and Duncan Grant, and others. Mr Sinclair takes his stand thus:

In terms of fundamental discoveries that would change our understanding of the structure of the world, the interchanges at the Kapitsa Club made the conversazione of the Society of the Apostles seem small beer. Science and technology derived from it would transform human societies, while the military application of atomic research would disturb international relations. Any political or social changes brought about by members of the Apostles could only be trivial. Yet the Apostles had the gift of the pen and the power of the word. They backed into publicity. Their clandestine doings became famous. Along with associates in Bloomsbury, rarely in the field of human endeavour has so much been written about so few who achieved so little. As for the Kapitsa Club, rarely in the field of human discovery has so little been written about so few who achieved so much.

In rebelling against the conventions of the past generation and looking inward with admiration upon themselves, the Society of the Apostles became vulnerable to invasion by Communism during the thirties, when the liberal-minded classes, if not some of the privileged classes, were very properly reacting against Nazism and Fascism. Burgess, Maclean, Philby and Blunt were Apostles converted to active Communism - a secret élite within a secret élite... Mr Sinclair traces their careers, through rightly being overt Soviet supporters when Russia was a major ally of the British during the war, to "moles" working their way, unvetted by virtue of |

Apostolic cachet, incredibly into British Intelligence when the West reverted to anti-Communism and the Cold War. Mr Sinclair estimates the military damage they did as trivial, exceeded by the damage done by Fuchs and Pontecorvo, "whose actions only accelerated inevitable discoveries by months or the odd year." More serious was the damage they did to the course of research in those sciences that were of interest to the politicians and the military in prosecuting the Cold War and the armaments race.

Mr Sinclair takes the point that until the tide turned with the advent of war, research was "open", its findings publicly available without restriction: the absence of restriction was, and still is, regarded by scientists as essential to the speediest and most effective advance of their research There was nothing secret about the discussions of the Kapitsa Club, and when Kapitsa was forcibly recalled to Russia in 1934 he took with him the common assumption that co-operation between his institute and the Cavendish would continue. That assumption was steadily eroded as the politicians and the military on both sides laid hands on nuclear physics; and it was in effect destroyed altogether in 1945 at the bombing of Hiroshima and Nagasakı: as Oliphant put it, "This has killed a beautiful subject". Mr Sinclair adds. "Fuchs's conviction on charges of espionage, followed by the defections of Burgess and Maclean, further soured the possibility of scientific collaboration. Espionage as usual had poisoned reciprocity. Treason was the enemy of reason." Well said! The story is a tragic one; the nature of science permanently marred by its use for unthinkable slaughter; human endeavour brought low by human weakness.

To end on a lighter note, let me earn my fee as a critic by finding fault. Occasional looseness in writing, for example "by months or the odd year". Occasional lapses of judgement, for example equating the damage of Fuchs and Pontecorvo - Fuchs actually was a nuclear physicist. whereas Pontecorvo's speciality was cosmic rays. Occasional failures in proofreading, for example "Sir Wallace Aken" was Sir Wallace Akers. For my taste too many names per inch of text — the index is a veritable list of All Those People You Would Like To Have Known But Never Had The Chance To Meet. And I began to feel that Mr Sinclair was tiring, his thinking becoming more dispersed, towards the end — when both cultures were themselves becoming more fragmented, more dispersed. Such fault-finding I simply dismiss in the face of the book's major achievement.

Observing arms control

Dennis Fakley

Verification: How Much is Enough? By Allan S. Krass. *Taylor & Francis: 1986.* Pp.271. £25, \$45.

CURRENT arms control treaties, such as the 1963 Partial Test Ban, 1967 Outer Space, 1972 Sea-Bed, 1972 Anti-Ballistic Missile, 1975 Biological Weapons and 1978 Environmental Modification agreements, contain little or no provision for cooperation between the signatories on measures to verify that the obligations in the treaties are being observed. This lack of verification provisions can be attributed either to the effectiveness of so-called national technical means of verification or to the relative unimportance of the treaties from a security viewpoint. Other treaties, which have been negotiated (but not ratified) or have been discussed - Threshold Test Ban, Peaceful Nuclear Explosions, Strategic Arms Limitations II, Comprehensive Test Ban, Chemical Weapons — are considered to be much more security-sensitive, and thus to require special measures to verify compliance. Western dissatisfaction with negotiated or proposed verification arrangements for these treaties accounts, in part, for the failure to complete them.

Any analyst of arms control verification is faced with a surfeit of American sources and a dearth of Soviet ones. In consequence, it is difficult to maintain a balance between American and Soviet views, upon which a verification regime has to depend. Professor Krass quotes extensively from American sources on both American and Soviet positions — without recognizing that the latter may be inaccurately reflected — and finds ample support for his conclusions.

In the Introduction, verification is taken to be the action of demonstrating compliance with treaty obligations. However, an arms control treaty usually requires the parties concerned to refrain from some specified activities rather than to undertake them; hence, verification has to be concerned with demonstrating an absence of non-compliance. As Professor Krass observes, a negative cannot be proved, but he could have pointed to the possibility of developing measures to provide sufficient assurance that treaty obligations were not being flouted.

The first main chapter, "Technology", is an account of the monitoring capabilities of satellite photography, ground-and satellite-based radars, seismology, nuclear explosion detectors, electronic signals interceptors and safeguards systems of the type operated by the Inter-

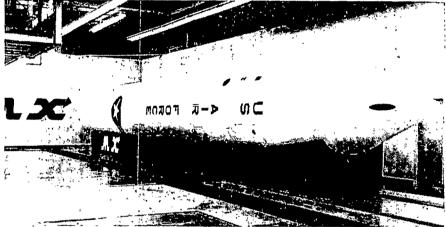

national Atomic Energy Agency (IAEA). While reference is made to some of the problems of achieving the theoretically available performances from these systems, such difficulties are largely discounted in the conclusion that a substantial number of arms control bans or limits could be verified with a high degree of reliability. This would not be universally endorsed.

In the next chapter, "Politics", Professor Krass outlines two major differences between the American and Soviet political approaches to arms control verification. He contrasts the American requirement, as a negotiating precondition, for assurance on the verifiability of an arms control measure, with the Soviet requirement for a definition of the measure to be negotiated before the question of

confident that any American attempt to circumvent a treaty would inevitably become public knowledge — and sooner rather than later.

American bureaucracy certainly complicates the process of arms control negotiation, and the separation of executive and legislative functions means that Presidential proposals are not necessarily enacted. This would not, however, appear to warrant Professor Krass's suggestion that verification provisions should be made less technically precise to avoid the risk of misunderstanding in Congress. On the contrary, precision is essential if the scope for genuine differences in interpretation is to be minimized.

It is undoubtedly true that the assessment of whether a verification regime is adequate depends on the prevailing politi-

Full-scale mockup of the MX intercontinental ballistic missile developed by the US Air Force

verification is discussed. He also compares their respective positions on on-site inspection, suggesting that they may be held for not entirely honourable reasons. He is, perhaps, over-optimistic about these differences becoming smaller.

Professor Krass appears to underestimate the importance of the fact that the closed nature of Soviet society militates against American confidence in treaty compliance. The American authorities recognize that, if the Soviet Union decided that it would be worthwhile violating an arms control obligation, it would not be constrained by public opinion. While not necessarily believing that the Soviet Union would deliberately enter into an agreement with the intention of disregarding its obligations, the possibility that it might do so leads the Americans to presume that treaty violations would occur unless they were made too unattractive by the verification provisions of the treaty. It is no argument to claim that the American intelligence services have been successful, in the post-war era, in penetrating the screen of Soviet military security. The successes are known but the failures may not be apparent until it is too late. On the other hand, the Soviet Union, no matter what it says, can be reasonably !

cal climate. This leads Professor Krass to conclude that unreasonable demands should not be made of the verification arrangements lest they become unacceptable with a change of political opinion. His conclusion is consistent with the underlying theme of the book, i.e. that arms control measures are needed so urgently that even risky compromises are justified if they lead to a negotiated agreement. He does not offer the option of postponing arms control agreements until robust verification measures become available.

It is highly questionable whether any real and stable arms control agreement can be reached as long as there is the present lack of trust between East and West, and Professor Krass rightly questions whether verification arrangements would build or undermine international confidence. He appears to believe that it needs a certain leap of faith to generate a modicum of trust between the superpowers to serve as a nucleus on which confidence could grow. Otherwise, verification arrangements are likely to reinforce existing prejudices. This is consistent with the view that it is futile to seek to resolve political differences between East and West by purely technical means; at best, they can only contribute to a process which has been politically initiated.

In the third and final main chapter. "Technology and Politics", Professor Krass attempts to correlate the technical and political issues he has raised. He examines the legitimacy of various verification technologies and sees the possibility of friction arising from the lack of an adequate international legal and institutional framework to regulate them. He also discusses how to deal with real and mistaken assessments of treaty non-compliance, and recommends that charges should be pursued vigorously only in cases where the suspected violation could have military significance; the political implications of breaches should largely be disregarded to avoid a threat to the continuation of the treaty. This would demand a tolerance which many might consider unrealistic. It would have been interesting to have had a deeper analysis of the different attitudes of the United States and the Soviet Union towards treaty compliance, and a recognition that "one man's compliance could be another's violation".

On-site inspection has for long been a bone of contention in arms control negotiation. Professor Krass argues that inspection rights have in some cases been sought for other than technical reasons, and that the effectiveness of on-site inspections in many arms control contexts has not been established. He predicts that there are insurmountable obstacles to any agreement on mandatory rights of inspection at other than pre-determined locations and that any inspection rights will be granted only when there is a reasonable degree of trust between parties to the treaty. Irrespective of the technical case for on-site inspection, politically it has become one of the measures by which the intentions of the Soviet Union will be judged.

Professor Krass deals only briefly with multilateral arms control but he would welcome an internationalization of verification. Here he fails to recognize that a sovereign state cannot possibly risk delegating to an international body responsibilities for activities that might impinge on its fundamental security interests. The safeguards regime operated by the IAEA does not provide a precedent.

If readers expect to find quantitative answers to the question posed in the title of this book, they will be largely disappointed. Professor Krass does, however, provide much relevant information in an easily digestible form and, so long as the reader recognizes the viewpoint from which he writes, the book will serve as a useful introduction to some of the issues of arms control verification.

Dennis Fakley, 14 Coval Gardens, London SW147DG, was formerly Assistant Chief Scientific Adviser (Nuclear) at the Ministry of Defence, and was Deputy Leader of the British Delegation during the 1977 – 1980 Comprehensive Test Ban negotiations. The opinions expressed in this review are his own.

Committee ecology

Michael J. Crawley

Ecological Knowledge and Environmental Problem-Solving: Concepts and Case Studies. Committee on the Applications of Ecological Theory to Environmental Problems, chairman Gordon H. Orians. National Academy Press, Washington DC: 1986. Pp. 388. Pbk \$24.50. Distributed in Britain by Wiley £28.60.

This is a curious book. Its origins lie in the recognition, by the Board on Basic Biology of the United States National Research Council's Commission on Life Sciences, that it should be concerned with the basic biology of ecosystems. The first aspect of ecology to receive the Board's attention was the current status of ecological concepts, and their applicability to specific environmental problems. Following a workshop in 1979, a committee was established under the chairmanship of Gordon Orians. This book represents the fruits of its labours.

There are two parts to the report. The first attempts to encapsulate "ecological knowledge" as it relates to environmental problem-solving. The second consists of 13 case-studies, selected to illustrate the use of ecological information in dealing with a wide variety of environmental problems. The intended audience is "those who prepare, receive, and use environmental evaluations and management plans; legislators and regulators concerned with environmental issues; and teachers and students in the natural and environmental sciences". Given this audience, the section "Kinds of Ecological Knowledge and Their Application" in the first part of the book has to be judged as unsatisfactory; it varies between being unacceptably shallow and downright misleading. A great many of the statements, though undoubtedly true (and probably both worthy and important), are so brief as to be unintelligible. Take this, for example: "many ecological interactions are characterized by strong non-linear effects brought about by slight changes in key factors". One would need a thorough grounding in theoretical ecology to get the real message.

A number of specious fallacies also get recycled in this part of the book. For example, on p. 28, we read that "the greatest number of individuals of a species that the environment can support is called the carrying capacity (K)". This is wrong; K is the equilibrium population size in models such as the logistic. In discrete-time versions of the logistic, overshoots of K are possible and perfectly reasonable, representing population sizes temporarily in excess of equilibrium. Again, on the same page, we find this gem: "Many pest

species, such as weeds, are poor competitors". Tell that to any gardener! Weeds are *exceptionally* competitive; rather, the point here is that many of them are short-lived, and also are rather unlikely to recruit from seed under shady conditions.

The second half of the book is much better, and the case-histories are carefully chosen and extremely interesting. They include well-known examples such as the biological control of California red scale, the Garki project on malaria control in West Africa, management of the North Pacific halibut fishery and the environmental effects of DDT. More recent studies include research on nuclear radiation, eutrophication, forest felling policy and wildlife managment. It would have been good to see more of them. allowing the inclusion of topics such as acid rain. desertification, release of genetically engineered organisms, the regulation of human population growth and so forth.

At the end of each case-study is a kind of headmaster's report by the editors. These "Committee Comments" are one of the highlights of the book, and have a delightfully superior tone about them -"relevant ecological theories, for the most part, proved inspirational or didactic, rather than directly applicable", or "it is interesting that the scoping of this project (and in fact, most of applied ecology) is somewhat myopic"! Another unintended bonus lies in a liberal sprinkling of parenthetical one-liners of the utmost inscrutability. For instance: "(if plants can be regarded as predators on photons)"; "(all predators must eat regularly)"; the guts of herbivores are "(technically outside their bodies, inasmuch as no cell membrane has to be crossed)"; or "(all CO2 molecules can be treated as identical)"!

The recommendations that emerge, however, are laudable. In carrying out environmental projects, managers are urged to: (1) involve scientists from the beginning; (2) treat projects as experiments; (3) publish information; (4) set proper boundaries on projects: (5) use natural history information; (6) be aware of interactions; (7) be alert for possible cumulative effects; (8) plan for heterogeneity in space and time; and (9) prepare for uncertainty and think probabilistically. This scheme would have made an excellent plan for the first section of the book, where the ecological principles underlying each of the recommendations could have been explained in context. As things are, however, the first half of the report is as weak as the second half is strong, and the book stands as a monument to the pitfalls of committee authorship.

AIDS without emotion

Peter Newmark

Mobilizing Against AIDS: The Unfinished Story of a Virus. By Eve K. Nichols. Institute of Medicine/National Academy of Sciences/Harvard University Press: 1986. Pp.198. Hbk \$15; pbk \$7.95. To be published in Britain on 18 August, hbk £12.75, pbk £6.75.

IT HAS become commonplace to describe as astounding the rate at which research on the AIDS virus has proceeded since the first isolation of the virus at the Pasteur Institute just over three years ago. The pace continues, so that the writer of any book on the subject faces an impossible task in trying to be fully up to date.

Although, in theory, handicapped in this regard by basing her book on a conference held in 1985, Eve Nichols has been able to add new information as recent as this April. Nonetheless, she has missed out on key new discoveries including that of a new gene in the virus and of what seems to be a second AIDS virus in some Africans. This just goes to prove the point about the rate of research, which is matched only by the rate of publication of books on AIDS. But Eve Nichols seems to have performed as good a job as anyone in writing a sensible account for an educated public.

The meeting to which the book owes its origins was the annual conference of the Institute of Medicine in the United States. There were about a dozen speakers, including both Luc Montagnier of the Pasteur — the only non-American — and Robert Gallo of the National Institutes of Health. Each of the eight chapters in the book is based on a few of the talks, and the scientific, medical and public health aspects of AIDS are all dealt with in a straightforward and unemotional way.

Care is taken to tread a middle course between the pessimists and the optimists on issues such as the rate of spread of AIDS in heterosexual populations and the prospects of effective vaccines or therapy. Adequate attention is drawn to such

• AIDS: Papers from Science, 1982 – 1985 is a collection of 108 research papers and reports, edited by Ruth Kulstad, that have appeared in Science. Arranged chronologically, the papers show the progress in AIDS research and indicate the directions in which it might go. An introduction by Dr Myron Essex, chairman of the Department of Cancer Biology at the Harvard University School of Public Health, provides an overview of AIDS research. Available from the American Association for the Advancement and Science, Marketing Dept. A, 1333 H St NW, Washington DC 20005, priced Hbk \$32.95, pbk \$19.95 plus \$1.50 p+p.

thorny questions as whether AIDS should be made a notifiable disease, so that contacts could be traced, when guarantees of confidentiality seem to have a way of being less than cast iron and when there is growing discrimination against even healthy carriers of the virus by employers and insurance companies.

The book comes complete with a glossary and a list of organizations (only American) to contact for help and information. Also included, as appendices, are the Public Health Service recommendations on preventing transmission in the workplace, care of infected children and reducing the risk of transmission. There is additional advice on how to prevent transmission, but none on how to put into practice one of the recommendations:

"Everyone should know the infection status of his or her sexual partners; those who are not infected should avoid intercourse with those who are infected".

Were this not a book aimed at the public, and particularly the public of the United States, it would be more fair to criticize the lack of recognition of some of the European contributions to the understanding of AIDS. In the same vein, it is a pity that less than two pages are devoted to the exceedingly serious problems of AIDS in Africa. But then, does the American public at large care about African AIDS? And for that matter, how many African countries would welcome a book such as this which dealt with their own AIDS problem for their own people? Peter Newmark is Deputy Editor of Nature.

Nimble electrons

David R. Rosseinsky

Hopping Conduction in Solids. By Harald Böttger and Valerij V. Bryksin. Akademie-Verlag, Berlin/Royal Society of Chemistry: 1986. Pp.398. DM 140, £44.

"LOVELY 'OPS", murmurs the drill sergeant quaffing a pint of beer in the television advertisement, while watching a platoon of recruits hop past him. So it is with electrons, which in certain solids move, and conduct, by hops from site to site. The other kind of electron motion, within the extended bands allowed by multi-centre wave functions pervading condensed matter, has curiously enough never acquired a complementary term like "swanning" or "floating" or even "shining": it is simply band conduction. Metals have it anyway, but crystalline semiconductors have bands only of high energy separated by a gap from the states populated by the bulk of electrons, which requires an energy input to mobilize the electrons. Most of the vast structure of solid state physics encompasses band systems, and the recent interest in hopping arose largely from the fact that amorphous semiconductors have irregular structures generating sites which are envisaged to lie within the gap. As these are more or less discrete from the bands, and each other. so are the motions of visiting electrons, hence the designation "hops". Nevill Mott's 1977 Nobel prize was in part awarded for his studies of amorphous semiconductors, and those who in the 1970s based their learning on Austin and Mott, and Mott and Davis, will be avid readers of the text at hand.

Professor Böttger in Magdeburg and Dr Bryksin in Leningrad have themselves contributed substantially to the subject and here provide a comprehensive account of the theory of the hopping mech-

anism. After elaboration of Hamiltonians for the hopping system, the small polaron model is described, in which the charge in question, together with the self-entrapping reciprocal effect on its ambience, represent the moving entity. The theoretical framework is then applied to observations on disordered systems. Ionic and atomic hopping are addressed next, and the final chapter is an up-dating of the material to mid-1985, inserted in proof as an addendum to the 1983 manuscript. This is perhaps not an entirely conformtable addition but it represents an excellent way of circumventing publication delays, fulfilling the aim of the series, of which this book is a member, to provide quick dissemination of information. Other authors and publishers could profitably follow suit. Part of the commendable immediacy has apparently been achieved by direct authorship without the intervention of a translator. Nearly a third of the references are those added in proof, which is indicative of the recent growth of interest in the mechanism.

If the book is somewhat austere in aspect it is quite readable withal. Few, however, who are not involved in the minutiae of conduction or electron transfer within solids will approach it lightly, but, besides physicists, solid state chemists will increasingly find the need for recourse to one or other aspect of the exposition. Siteto-site electron transfer occurs in (chemical) mixed-valent solids where the sites are regular and rigorously defined, but such promising, even ideal, routes towards verifications of the theories have not yet entered the province of the monograph. Biological electron transfer between donor and acceptor sites is of the same kind as that considered here, and so the ramifications of this quite complex motion will extend across the sciences perhaps by discrete hops.

Geochemical constraints on core formation in the Earth

John H. Jones & Michael J. Drake

Lunar and Planetary Laboratory, University of Arizona, Tucson, Arizona 85721, USA

New experimental data on the partitioning of siderophile and chalcophile elements among metallic and silicate phases may be used to constrain hypotheses of core formation in the Earth. Three current hypotheses can explain gross features of mantle geochemistry, but none predicts siderophile and chalcophile element abundances to within a factor of two of observed values. Either our understanding of metal-silicate interactions and/or our understanding of the early Earth requires revision.

CORE formation has been described as perhaps the single most important thermal event in the history of the Earth¹. This description is certainly true if the core formed by segregation of metal in an initially homogeneous body the size of the present Earth, as the heat liberated in such an event would raise the temperature of the Earth by ~2,000 °C (ref. 2). However, less extreme models in which core formation is concomitant with accretion appear to be more probable³. Regardless of whether core formation resulted in catastrophic changes in the Earth. better knowledge of the core-forming event would certainly elucidate important aspects of the histories of the Earth and Moon⁴.

Geochemists have traditionally divided the chemical elements into four classes: (1) lithophile—those elements which prefer to be combined with oxygen and which typically reside in rocky material; (2) siderophile—elements which prefer to be in the metallic state; (3) chalcophile—elements preferring to be associated with sulphur; and (4) atmophile—elements so volatile that they are typically concentrated in a planet's atmosphere. Obviously, membership in one of these classes is not invariant, but is modulated by the ambient conditions. For example, as the temperature increases, elements which normally exist as solids or liquids will vaporize and become gases, and, in fact, the classes of lithophile, siderophile and chalcophile are typically subdivided into groups of elements of similar volatility.

In principle, the record of core formation is contained in the siderophile and chalcophile element contents of rocks derived from the Earth's mantle. Certainly these elements are much more depleted in the upper mantle than lithophile elements of similar volatility, implying that they record a depletion event unseen by the lithophile elements—presumably core formation. In practice, these elemental abundances have been attributed to either gross disequilibrium between the core and upper mantle, or mixing of siderophile- and chalcophile-element-rich material into the upper mantle after core formation, or both^{5,6}. In this view, little information about core formation may be obtained from mantle siderophile and chalcophile elements because their abundances were established either after core formation ceased or as the results of processes which never approached equilibrium. The evidence cited for disequilibrium between mantle and core during core formation is simply that the concentrations of siderophile and chalcophile elements in mantle-derived rocks are orders of magnitude higher than would be expected if these rocks had ever equilibrated with metal⁶. Furthermore, many of the siderophile elements in the Earth's mantle exist in chondritic proportions (that is, with elemental abundance ratios characteristic of primitive meteorites (chondrites) which have not undergone chemical processing). Thus, successful models of core formation and for siderophile and chalcophile element abundances in the Earth's upper mantle must be able to explain both high abundances and the apparently unfractionated ratios of some (but not all) element pairs.

Models of core formation are further complicated by our lack of knowledge of the chemical composition of the core. All models of the Earth's core require the presence of a 'light element' to reduce the overall density³. If the light element is sulphur, silicon or carbon, then these elements were probably dissolved into the metal (which eventually formed the core) at low pressure as the Earth grew by accretion, and may be relevant to understanding the core-forming process. If the light element is oxygen or a mixture of oxygen and lithophile elements which have followed oxygen into the core, then the light element must have been incorporated at high pressure⁴ and may not have played a role in establishing the siderophile and chalcophile element abundances of the upper mantle.

The behaviours of siderophile trace elements in complex, natural metal-silicate systems are poorly known. This lack of knowledge has led us to determine partition coefficients (Ds; for definition, see below) between solid metal, sulphur-bearing metallic liquid and silicate liquid for a suite of siderophile and/or chalcophile elements under controlled laboratory condi- $(T = 1,250-1,270 \,^{\circ}\text{C};$ $P \leq 1$ bar). These partition coefficients, together with estimates of the mantle abundances of the same elements, may be used to evaluate three physically plausible but very different hypotheses of core formation. These hypotheses are: (1) inefficient core formation, involving equilibrium between solid and liquid metals and silicates, with a small fraction of solid and liquid metal remaining trapped in the mantle, subsequently to be oxidized7; (2) equilibrium between an Fe-S-O metallic liquid and the mantle⁸; and (3) heterogeneous accretion involving a late 'veneer' of oxidized chondritic material which did not segregate into the core^{6,9}. In each of these hypotheses, metal is added to the surface of the growing Earth, and initial interaction between metal and silicate will occur at relatively low pressures. Hence, our partition coefficients, which are obtained at low pressure, may be applicable. Later, we shall return to this point and further discuss the importance of pressure on partitioning equilibria.

A fourth hypothesis, that siderophile and chalcophile element abundances in the Earth's upper mantle were established by partitioning between metal and silicate at very high pressures, perhaps at the core-mantle boundary, will not be explored for three reasons. First, metal-silicate partition coefficients have not been determined at megabar pressures, precluding quantitative evaluation. Second, evidence discussed below suggests that siderophile and chalcophile element concentrations in the mantle were established no later than 3.5 Gyr ago. Thus, material must have been efficiently cycled from the core-mantle boundary to the upper mantle and have been well mixed in <1 Gyr. Such effective mixing appears problematical. Third, it seems unlikely that equilibration of siderophile elements between the core and lower mantle would have preserved chondritic ratios of elements such as Ni and Co, which differ greatly in their siderophile tendencies.

	Table 1 Experimental conditions and results

- * Calculated from the Fe content of the solid metal and the FeO content of the silicate glass using the iron-wüstite data of ref. 41.
- ‡ Weight per cent sulphur in liquid metal phase.
- § Number of individual experiments which contained silicate melt.
- All experiments contain Ni but only one sample (the most oxidized sample to receive a high-neutron-flux irradiation) contained measurable Ni in the silicate glass. The range for $D_{(LS/LM)}$ is that for two analyses of the same glass.
 - ¶ Below detection limit.

The first three hypotheses will be explored in more detail. First, however, we will discuss constraints obtained from experimental and natural samples which must be satisfied by any successful model of core formation in the Earth.

Constraints

Partition coefficients. Our experimental partitioning techniques have been described elsewhere 10 and will not be repeated in detail here. In general, samples containing Fe-Ni metal, natural pyrite (FeS₂), synthetic basaltic glass and a tracer element are placed in an alumina crucible and sealed in an evacuated silica tube with a separate Fe-metal-silica assemblage designed to maintain the oxygen fugacity of the system (f_{O_2} , equivalent to the partial pressure of oxygen) near the quartz-fayalite-iron (QFI) buffer (thus ensuring that iron metal is a stable phase). Quenched samples of coexisting solid metal (SM), liquid metal (LM) and liquid silicate (LS) are analysed by electron microprobe. If the tracer concentration in the silicate glass is too low for microprobe analysis, aliquots of glass are separated from metal and analysed by instrumental neutron activation. Table 1 gives experimental conditions and results for W, Re, Ir, Mo, Ni, Co, Au, P, Ga, Ag and Pb—a suite of elements which covers a wide range of nebular condensation temperatures (volatilities) and geochemical behaviour. In this suite W, Re and Ir are the most refractory and Ag and Pb are the most volatile.

Siderophile abundances in the bulk Earth. The presumed extraction of most of the siderophile and chalcophile elements to the core makes calculation of the bulk-Earth concentrations of these elements difficult or impossible. However, on the basis of lithophile elements, which do not readily combine with Fe or S, we infer that the bulk Earth is approximately chondritic in composition. We do not mean to imply by this that the Earth is compositionally identical to the group CI chondrites, but that refractory siderophile elements should be present in chondritic relative proportions and that more volatile elements may be depleted to varying degrees. Figure 1 shows the concentrations of siderophile and chalcophile elements in several types of chondritic meteorites. Refractory siderophile elements are usually present in higher concentrations than in group CI, while more volatile elements are typically depleted. Again, although the concentrations of siderophile and chalcophile elements in the bulk Earth are unknown, it is reasonable to require that models of bulk-Earth abundances of these elements be consistent with siderophile and chalcophile element concentration patterns in chondrites.

Siderophile abundances in the upper mantle. During the past decade, a large quantity of high-quality data on mantle samples (such as lherzolites) and basalts has become available. Morgan

et al.⁶ and Jagoutz et al.¹¹ have presented convincing evidence that their lherzolite samples (or at least their most 'fertile' lherzolite samples) have not undergone large amounts of partial melting, and hence are most likely to record primitive mantle abundances, at least for the compatible elements. Thus, when possible, we have used the mantle abundance estimates of refs 6 and 11. For the incompatible elements P, Mo and W, abundances are inferred from the trace-element systematics of basalts (see below). These estimates are listed in Table 2.

Mineral-melt partitioning in basalts. The partitioning of Ni and Co and between minerals and silicate melts is moderately well known from laboratory experiments, but these elements are the exception rather than the rule. For most of the elements in our suite, solid silicate (SS)/liquid silicate (LS) partition coefficients for element i (${}^{i}D_{SS/LS}$) must be evaluated from element correlations in natural basalts. For example, a comparison of data for basalts and ultramafic xenoliths on Re versus Ir and Au versus Ir diagrams from ref. 12 implies that ${}^{Au}D_{SS/LS}$ and ${}^{Re}D_{SS/LS}$ are of order unity, but that ${}^{Ir}D_{SS/LS}$ is ~ 50 . (Note in Table 1 that during core formation, trivially small fractions of Au, Re or Ir enter the silicate phase, making the exact value of these particular silicate partition coefficients of little consequence. Also, although the host phase of Ir during silicate partial melting is unknown, the large differences in partitioning behaviour between Au and Ir strongly imply that the host is an oxide or silicate.)

Drake¹³ has used element *i* versus La diagrams to make geochemical distinctions between terrestrial, lunar and eucritic basalts. Many siderophile and chalcophile elements, when plot-

- * Concentrations normalized to CI chondrite ref. 43.
- † Mean of total Pb and unleachable Pb.

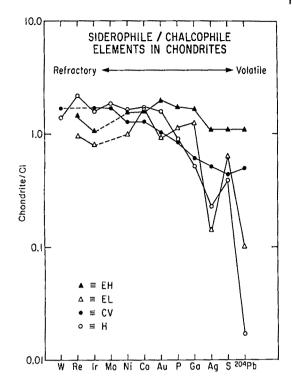

Fig. 1 Siderophile and chalcophile element abundances for four different types of chondritic meteorites (A, EH; △, EL; ●, CV; O. H), normalized to the concentrations of these elements in CI chondrites. Elements on the left are more refractory and elements on the right are more volatile. Relative to CI chondrites, refractory siderophile and chalcophile elements are typically enriched in other chrondrite types and volatile siderophile and chalcophile elements are typically depleted. Chondritic materials provide estimates of the siderophile and chalcophile element abundances that may be expected in the bulk Earth (see text). Data are from the following sources: E, chondrites, refs 45 (Re, Ir, Ni, Au, Ag), 43, 46 (Co, Ga), 43, 47 (P), 43, 48 (S), 43, 49 (204 Pb); CV, chondrites, refs 50 (Ir, Co, Ni, Au, Ga), 43, 51 (Re, Ag), 43, 52 (W), 53 (Mo), 43, 47 (P), 43, 54 (S), 43, 55 (204 Pb); H chondrites, refs 43, 56 (W, Re, Ir, Mo, Ni, Co, Au, P, Ga, S) 43, 57 (Ag), 43, 58 (204 Pb). When only one reference is given, both the chondrite group analysis and the CI normalization analysis are reported in that reference. When two references are given, the first is the source of the CI normalization.

ted on such a diagram, form linear trends which yield information on the depletion of element i in the mantle (relative to chondritic abundances) and permit the partition coefficient of i between basalt and mantle residuum to be estimated. For example, Ga concentrations in basalts increase by a factor of two, while La concentrations increase by two orders of magnitude in natural terrestrial samples¹³. If we assume that this basalt trend is formed by differing degrees of equilibrium partial melting of similar mantle sources and that $^{\text{La}}D_{\text{SS/LS}} \leq 10^{-2}$, then $^{\text{Ga}}D_{\text{SS/LS}} \simeq 0.4$. Correlations of Pb with La show almost exactly the same variation as the Ga-La diagram, implying that Pb Dss/Ls is also ~ 0.4 . The good (approximately 1:1) correlation of P, W and Mo with La or another lithophile incompatible element in basalts^{14,15} implies that these elements are all very incompatible in silicate systems. Diagrams of phosphorous, W and Mo versus incompatibile elements are also the best means of ascertaining the mantle abundances of these elements 14,15. Analyses of Ag in terrestrial basalts are very scarce; however, based on the available data16,17, Ag appears to be weakly incompatible like Ga and Pb. Consequently, we have adopted a value of $^{Ag}D_{SS/LS} =$ 0.4, although it could be larger. For example, the MORB (midocean-ridge basalt) data of ref. 17 are consistent with values of $^{\mathrm{Ag}}D_{\mathrm{SS/LS}}$ between 0.1 and 0.5, for 5% equilibrium partial melting.

Summary. Table 3 lists our adopted partition coefficients. As we shall see below, the uncertainty associated with these partition coefficients, while often large, is of the same order as the uncertainties regarding the physical conditions under which core formation occurred. In this sense at least, we feel that zeroth-order modelling, using the data of Tables 2 and 3, is justified. We will now examine hypotheses for core formation in the light of these data.

Hypotheses

Inefficient core formation. The segregation of the core from the mantle is envisaged as an equilibration between four phases, namely, solid silicate, liquid silicate, solid metal and liquid metal, followed by incomplete separation of metal from silicate. Equilibrium between these four phases is described by three sets of partition coefficients (D) for each element at specified temperature, pressure and oxygen fugacity: D(solid metal/sulphur-bearing metallic liquid), D(liquid silicate/sulphur-bearing

Element	$D_{(LS/LM})$	$D_{(SM/LM)}$	$D_{\rm (SS/LS)}$

* Calculated from our data and that of ref. 25.

metallic liquid) and D(solid silicate/liquid silicate) where ${}^{i}D_{(\alpha/\beta)}$ is defined to be the weight concentration of element i in phase α divided by the weight concentration of element i in phase β .

The partitioning behaviour of the elements in the experimental suite can be generalized in the case of this hypothesis. Mantle concentrations of Au, Ir, Mo, Ni and Re are determined almost solely by the amount of trapped metal phases. Silver is concentrated nearly exclusively in the trapped metallic liquid; P, W, Ga, Co and Pb are intermediate in their siderophilic tendencies. Nickel, Co and Ir and compatible $(D_{SS/LS} > 1)$ in solid silicates (or oxides); W, P and Mo behave as very incompatible elements $(D_{SS/LS} \ll 1)$; and other elements are intermediate in their silicate-system compatibility.

Physical conditions of core formation. The fractions of metal and silicate in the Earth are taken to be 0.3 and 0.7, respectively, the relative masses of the present core and mantle. The proportions of solid metal and liquid metal are determined by assuming that the principal light element in the core is sulphur. Our experiments (see below) were conducted so that our metallic liquids contained ~25 wt% S. Thus, if the present core contains 8-12 wt % S (ref. 18), use of our experimental data in model calculations requires that the metal assemblage which segregated to form the core was 30-50% molten at the time of metal-silicate equilibration.

The degree of partial melting of silicate materials during core formation is virtually unknown. If the Earth's accretion and core formation occurred rapidly, it seems inconceivable that high degrees of partial melting could have been avoided'; however, the mantle samples themselves give no evidence for extensive melting early in the Earth's history. Spinel lherzolites throughout the world are very similar in composition and

[†] Ni and Co $D_{\rm (SS/LS)}$ values estimated from ref. 44; all others estimated from natural basalt systematics (see text).

texture¹⁹. If lherzolites are undepleted in elements that are strongly concentrated in basalts, these lherzolites are described as 'fertile' (that is, able to produce basalt). Large chemical differences are not observed between the fertile spinel lherzolites and the fertile garnet lherzolites¹⁹. Small differences between garnet and spinel lherzolites may exist²⁰, but the overall chemical similarity between these rock-types implies a mantle which is chemically homogeneous down to at least the depth of the sources of garnet lherzolites (~150 km; ref. 21). If large degrees of partial melting (>20%) occurred in the early Earth, even minor density differences between solid and melt would be expected to lead to phase separation and the formation of a magma ocean²². Subsequent crystallization of this hypothetical magma ocean would be unlikely to result in a chemically homogeneous upper mantle. Rather, it would be expected that the formerly molten portion of the mantle would resemble large mafic intrusions with pronounced vertical zoning, as observed in the Stillwater and Skaergaard intrusions and inferred for the Moon^{23,24}. Even if such zoning was largely homogenized by subsequent mantle convection, it is surprising that apparently no remnants remain within the continental lithospheres. The uniform chemical composition of mantle lherzolites (the samples from which our mantle siderophile and chalcophile element abundances are mainly derived), coupled with plausible physical theories of core formation which predict continuous core formation as the Earth grows from the mass of Mars to its present mass³, lead us to opt for low degrees (≤20%) of silicate partial melting.

The ambient oxygen fugacity during core formation was most likely below the iron-wüstite (IW) oxygen buffer (see later discussion), but is otherwise imprecisely constrained. Thus we allow for isothermal variation in oxygen fugacity in our coreformation model. In practice, this means that we allow $D_{\rm LS/LM}$ to change with oxygen fugacity in an ideal manner, as defined by Rammensee²⁵. The $^{1}D_{\rm LS/LM}$ values in Table 3 are appropriate for a log $f_{\rm O_2}$ of -12.75 at 1,250-1,270 °C (approximately one log unit below the QFI oxygen buffer).

Model calculations. The inefficient core formation hypothesis may be tested mathematically using the formalism outlined below:

(1) After equilibration among the four relevant phases, most of the solid and liquid metal drains away and does not communicate further with the overlying mantle. This process is subject to the constraint of mass balance, so that

$${}^{t}C_{\text{Earth}} = {}^{t}C_{\text{SM}}X_{\text{SM}} + {}^{t}C_{\text{LM}}X_{\text{LM}} + {}^{t}C_{\text{SS}}X_{\text{SS}} + {}^{t}C_{\text{LS}}X_{\text{LS}}$$
 (1)

where Xs are mass fractions, ${}^{i}Cs$ are mass concentrations of element i and SM, LM, SS and LS refer to solid metal, liquid metal, solid silicate and liquid silicate, respectively. Reiterating the constraints outlined above,

$$X_{\rm SS} + X_{\rm LS} = 0.7 \tag{2}$$

$$p = X_{LS}/(X_{SS} + X_{LS}) \le 0.2$$
 (3)

$$X_{\rm SM} + X_{\rm LM} = 0.3 \tag{4}$$

$$0.3 \le X_{LM} / (X_{LM} + X_{SM}) \le 0.5$$
 (5)

where p is the fraction of the silicate portion of the system which is molten. In terms of partition coefficients (D) and degree of partial melting, equation (1) becomes

$${}^{i}C_{Earth} = {}^{i}C_{LM}[{}^{i}D_{SM/LM}(0.3 - X_{LM}) + X_{LM} + 0.7{}^{i}D_{SS/LM}(1 - p) + 0.7{}^{i}D_{LS/LM}p]$$
(6)

As partition coefficients have been measured, ${}^{l}C_{Earth}/{}^{l}C_{LM}$ may be calculated for assumed values of p and X_{LM} . The sensitivity of this calculation to the assumptions of equations (2)–(5) should, in general, be acceptably small. For example, the permissible variation in the total masses of the various reservoirs (solid metal, liquid metal, and so forth) is probably about a factor of

two, and the effects of factor-of-two uncertainties translate into two-fold changes in calculated concentrations.

(2) A small amount of trapped solid metal (X'_{SM}) and trapped liquid metal (X'_{LM}) remains behind in the upper mantle. The concentration of element i in the mantle is then given by

$${}^{i}C_{\text{mantle}} = {}^{i}C_{\text{LM}}X'_{\text{LM}} + {}^{i}C_{\text{SM}}X'_{\text{SM}} + {}^{i}C_{\text{SS}}(1-p) + {}^{i}C_{\text{LS}}p$$
 (7)

if X'_{SM} and X'_{LM} are small (~0.01).

Rearranging as in equation (6), we obtain

$${}^{i}C_{\text{mantle}} = {}^{i}C_{\text{LM}} \left(X'_{\text{LM}} + {}^{i}D_{\text{SM/LM}} X'_{\text{SM}} + {}^{i}D_{\text{SS/LM}} (1 - p) + {}^{i}D_{\text{LS/LM}} p \right)$$
(8)

(3) As ${}^{i}C_{\text{mantle}}$ is known from mantle nodules and basalts, ${}^{i}C_{\text{LM}}$ may be calculated for assumed values of p, X'_{LM} and X'_{SM} . If ${}^{i}C_{\text{LM}}$ is known then ${}^{i}C_{\text{Earth}}$ can also be calculated from equation (6). The credibility of the chosen values for the model parameters may be evaluated by comparing the calculated ${}^{i}C_{\text{Earth}}$ to the concentration of element i in CI chondrites (${}^{i}C_{\text{CI}}$). Values of ${}^{i}C_{\text{Earth}}$ for refractory elements which deviate by an order of magnitude from 2-3 × ${}^{i}C_{\text{CI}}$ are defined as unacceptable, and new values for the model's parameters are chosen.

There are five important adjustable parameters: $X_{\rm LM}$, p, $f_{\rm O_2}$, $X'_{\rm LM}$ and $X'_{\rm SM}$. However, it must be emphasized that it is unknown in detail if the measured partition coefficient values are exactly appropriate. We note that low-pressure (1 bar) partition coefficients may be relevant, in that new metal accreting to the Earth is deposited at the surface, and metal-silicate equilibrium is likely to be achieved at relatively shallow depths before the metal largely segregates into the centre of the growing planet. Nevertheless, we should probably be content if any set of model parameters can be found which, assuming an Earth with chondritic relative proportions of refractory elements (2-3 × CI), will predict mantle abundances of siderophile and chalcophile elements to within a factor of two. Better fits, while mathematically pleasing, may have no physical significance.

Results. Jones and Drake⁷ have evaluated inefficient core formation as a means of reconciling the high abundances of siderophile and chalcophile elements in mantle materials with a reducing (that is, low- f_{O_2}) core-forming event. Early results were encouraging, but increasing the number of constraints on the model (that is, increasing the number of elements to be modelled) has led to progressively poorer model results. Figure 2 shows a 'best fit' calculation of bulk-Earth concentrations for our suite of siderophile and chalcophile elements. The refractory elements W to Mo have concentrations of $\sim 2 \times CI$ in the bulk Earth, a reasonable value. The more volatile elements show various degrees of depletion. Au and P concentrations appear low compared with those of more volatile elements.

Calculated Co and Ni abundances are such that the Co/Ni ratio in the Earth is within 10% of chondritic (a requirement of our model), but this agreement is somewhat contrived as Co and Ni are not concentrated in the same phase. Nickel is contained mainly in the metallic phases, whereas Co is retained by the silicates. Maintaining a chondritic Ni/Co ratio in the bulk Earth by our model requires trapping large amounts of metallic liquid (~2.5 wt %) in the mantle. Although this amount of trapped liquid is not inconsistent with theoretical estimates²⁶, the retention of this S-bearing liquid leads to unreasonably high S concentrations (~6,000 p.p.m.) in the mantle, in contrast to the observed concentration of <300 p.p.m. S (ref. 19).

Furthermore, because we allow for isothermal variation in oxygen fugacity (and, therefore, in ${}^{i}D_{LS/LM}$ as well), our best-fit oxygen fugacity is $\sim 1-1.3$ log units more oxidizing than the oxygen fugacity necessary for the present mantle FeO concentrations to have been established by equilibration with metal at 1 bar. This disagreement is not necessarily a problem, as an oxygen buffer such as QFI will become slightly more oxidizing with pressure (by ~ 1 log unit per 50 kbar), but more work is needed to define the relative effects of pressure and oxygen fugacity on siderophile and chalcophile element partitioning.

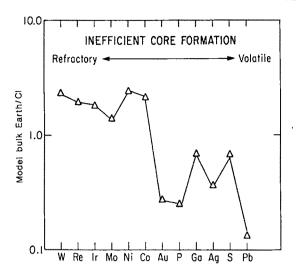

Fig. 2 Calculated bulk-Earth abundances of a suite of 12 siderophile and/or chalcophile elements. Elements are listed in the same order as in Fig. 1. The model of calculation is that of inefficient core formation (see text). The physical conditions of core formation and the amount of trapped metal phases are varied until the calculated refractory siderophile element abundances are 2-3×CI for the bulk Earth and the Ni/Co ratio of the bulk Earth is within 15% of chondritic. Clearly, geologically reasonable conditions can be chosen so that these two constraints are satisfied. A consequence of the calculation is that volatile elements are found to be depleted in the bulk Earth. A drawback of this type of model is that calculated S abundances for the upper mantle are >20 times higher than is actually observed. Best-fit model parameters: trapped metallic liquid (25 wt% S), 2.5%; trapped metal, 0.04%; degree of silicate partial melting, 10%; $\log f_{\rm O_2} = -12.35$; S concentration in core, 10%

Thus, even though it is possible to calculate bulk-Earth concentrations of many siderophile and chalcophile elements which are not unreasonable, the consequences of inefficient core formation are not totally attractive. If this model is to be viable, there must be substantial changes in the values of partition coefficients due to an uninvestigated intensive variable (such as pressure). Such variations are certainly not out of the question, especially as the Fe-FeS eutectic composition is known to be pressure-sensitive²⁷.

Equilibrium between an Fe-S-O metallic liquid and mantle silicates. This model has been proposed by Brett⁸, and accounts successfully for the upper-mantle abundances of a subset of siderophile and chalcophile elements. The model postulates equilibrium between metal and silicate phases and does not resort to trapping small fractions of metal in the mantle. The main difference between this model and previous equilibrium core-formation models is that no solid metal is present. It recognizes that liquid metal/silicate partition coefficients may be lower than solid metal/silicate partition coefficients (Table 3). The redox conditions postulated by Brett⁸ are rather oxidizing, in accordance with the absence of solid metal. This model is mathematically testable using partition coefficients and mass balance constraints in a similar manner to that outlined above. Generalizations concerning element partitioning are also as above.

Although at first sight this hypothesis seems successful, there are significant difficulties which appear to invalidate it. For example, the refractory element Mo was calculated by Brett⁸ to be present in the Earth's mantle at $59 \times \text{CI}$ abundance. Although this value is much closer than typical fits obtainable with solid metal/silicate partition coefficients, we consider this to be an unacceptably high value. In addition, although unknown to Brett⁸ at the time, the value of 3.65×10^{-3} which he used for the Ni liquid silicate/liquid metal partition coefficient is very large

(compare with our value of 2×10^{-4} in Table 3) and, in turn, implies an oxygen fugacity too high to be consistent with the low FeO content of the Earth's upper mantle. For example, at 1,250 °C, we predict that the oxygen fugacity required for Brett's Ni partition coefficient is ~ 1 log unit more oxidizing than the Fe-FeO (IW) oxygen buffer. Under these conditions, the activity of Fe in an Fe-S-O metallic liquid will be much less than the activity of FeO in any coexisting silicates. The very low iron content of the upper mantle (<10 wt %) implies that any metallic liquid postulated to have been in equilibrium with the upper mantle (under oxidizing conditions) had an even lower iron activity than the present mantle.

The possibility that core formation in the upper mantle occurred by separation of a metallic liquid with a very low iron activity deserves further exploration. In the Fe-Si system at 1,600 °C, for example, the iron activity at the midpoint of the binary system is ~0.05 (ref. 28). In the Fe-S system at 1,600 °C the iron activity at the midpoint of the system is ~ 0.13 (ref. 29). Non-ideal interactions between iron and non-metals can drastically reduce the activity of iron, even at fairly high iron concentrations in the liquid. Conversely, decreasing the temperature may minimize the non-ideal effects of non-metals. For example, at the eutectics of the Fe-S and Fe-Si systems, where the mole fraction of iron is definitely less than unity, iron metal is stable and the activity of iron in the liquid must also be unity. The complex interaction of intensive variables (pressure, temperature, non-metal concentrations, oxygen fugacity) make quantitative prediction of liquid activities difficult.

Although we cannot rule out highly oxidizing conditions during core formation on physical-chemical grounds, we note that fractionations of the noble refractory siderophile elements are much more probable in this model than in other models of core formation. Because noble siderophile elements appear to be present in chondritic relative abundances in the Earth's mantle, this is an important consideration. In the inefficient core formation model, mantle abundances of the noble refractory siderophile elements are 'buffered' towards chondritic ratios by trapped metal, contrary to the assertion of Morgan³⁰. In 'late-stage veneer' models , of course, no noble siderophile element fractionations are possible because the material is simply added to the upper mantle without chemical processing.

Figure 3 shows the results of recalculating bulk-Earth abundances for Brett's model by extrapolating our internally consistent set of partition coefficients to higher $f_{\rm O_2}$. In this model $X_{\rm LM}=0.3$, the degree of silicate partial melting is 20%, and $f_{\rm O}$ is allowed to vary between IW and QFM (quartz-fayalite-magnetite, an oxidizing buffer at which iron metal is unstable). Our inefficient core formation model results from Fig. 2 are shown for comparison. The refractory siderophiles (W, Re, Ir, Mo), rather than being enriched relative to CI, are severely depleted. We conclude that Brett's equilibrium core formation model is no more viable than our own, although this conclusion is subject to the same caveat as before—that high-pressure partitioning data are virtually non-existent.

Heterogeneous accretion/'chondritic veneer'. The most recent advocates of this type of model are Morgan et al.6 and Wänke9, who have suggested that material accreted to the Earth became progressively more oxidized as accretion proceeded. Early accretion and core formation was dominated by highly reduced materials, and metal effectively segregated siderophile and chalcophile elements to the centre of the growing planet. By the end of accretion, an influx of more oxidized materials had caused core formation to cease because metal was no longer stable. In this model, moderately siderophile elements such as Ni and Co stopped segregating to the core when the Earth's accretion was 80-90% complete; the noble siderophile elements such as Ir and Au ended their segregation into the core when accretion was ~99% complete. This model predicts that moderately siderophile elements should be present in the mantle in chondritic ratios, at abundances of 0.1-0.2 × CI, and that the noble

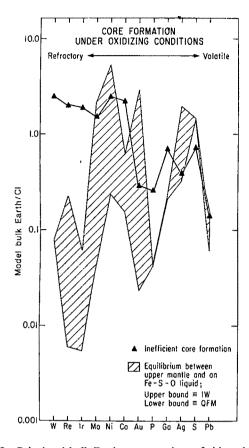

Fig. 3 Calculated bulk-Earth concentrations of siderophile and chalcophile elements assuming equilibrium between an Fe-S-O liquid and a mantle which is 20% partially molten (T=1,250 °C). The shaded region shows the calculated concentrations for a range of oxygen fugacities, ranging from IW (upper bound) to QFM (lower bound). Bulk-Earth abundaces calculated by the inefficient core formation model are shown for comparison (Δ). The assumption that the core formed in relatively oxidizing conditions, without any trapping of metals by the mantle, leads to the conclusion that the Earth is depleted in refractory siderophile elements, contrary to the expectations based on Fig. 1.

siderophile elements should be present in chondritic ratios at $\sim 0.01 \times CI$ abundances.

This class of hypothesis has gained favour in the past decade, in spite of the requirement that extensive physical mixing of material into the upper mantle must occur after core formation. Impact processes alone seem incapable of such fine-scale mixing (witness the heterogeneity of meteorite-derived siderophile elements in lunar samples), but sustained sub-solidus mantle convection may be adequate, particularly if mantle convection is layered. The mixing process must be capable of homogenizing Fe, Co and Ni at the scale of basalt generation by 3,500 Myr BP and be capable of homogenizing Ir at the hand-sample scale by today^{7,31}.

In this regard, it is possible that samples of the upper mantle which have been stored in continental lithospheres for considerable times (without the benefit of sub-solidus convective mixing over geological time) place even tighter constraints on the rate of mixing required to homogenize mantle siderophile elements. Jagoutz et al.³² have presented evidence that 2,700 Myr-old eclogites have been stored in the lower continental lithosphere for long periods of time (100-2,000 Myr) without participating in mantle mixing processes. More dramatically, Boyd et al.²¹ have argued that eclogitic and garnet peridotitic material, transported to the surface by kimberlite eruption, was emplaced in the lower continental lithosphere as long ago as 3,000-3,500 Myr. Thus, it is quite possible that the isolation of con-

Table 4 Test of the multi-component accretion model

Element	Concentration before second episode of core formation (C/CI)	Concentration after removal of metal* (C/CI)
Ni	0.2	0.2
Co	0.2	0.2
P	0.2	0.2
Mo	0.2	0.064
Ga	0.2	0.2
W	0.2	0.2

^{*} Just enough metal is removed to lower the Mo concentration from 0.2 to 0.064×CI (see text).

tinental shield lithospheres from mantle convection and the homogenization of Ir that we observe today in continental lithospheric materials were both complete by 3,500 Myr ago. We question whether mantle convection was capable of such rapid, fine-scale mixing.

Another way of making the same observation is to note that Ir contents of Iherzolites from beneath old cratons (such as Southern Africa), from beneath younger continental margins (such as the southwestern United States) and from mantle overlying oceanic hot-spots (Hawaii) are essentially identical¹⁹. The lithospheres beneath southern Africa and the southwestern United States were not obviously isolated from mantle convection at the same time, and the lithosphere beneath Hawaii has presumably never been isolated to the same degree as continental lithospheres. Iridium homogenization was apparently complete by the time of the formation of the earliest continental lithospheres.

Regardless of absolute rates of mantle mixing, the moderately siderophile elements are a sensitive test of the heterogeneous accretion hypothesis. Table 4 shows our model results using the partition coefficients of Table 3. For simplicity we have quantized accretion and core formation (before the accretion of the last 1%—the hypothesized 'late-stage veneer') into two parts: the first 80% of material accreted is highly reduced, the last 20% is more oxidized. This approach permits us to model core formation as two discrete events: the first, which removed all siderophile and chalcophile elements from the early-accreted 80% of the Earth, and a second event which removed only noble siderophile elements (such as Ir and Au) from the late-accreted 20%. A justification of this simple approach is that, because of the large difference in the metal/silicate partition coefficients between Co and Ni, continuous core formation during the last 20% of accretion would be unlikely to preserve the approximately chondritic Co/Ni ratio of the upper mantle (Table 2). Thus, at the beginning of the second model core-forming event, most (if not all) siderophile and chalcophile elements were present at $\sim 0.2 \times CI$ abundances in the upper mantle, as defined by present Ni and Co abundances. At this time we allow just enough separation of metal to lower the Mo concentration from 0.2×CI to its present value of 0.064×CI (Table 2), and we observe the effect of this separation on the other siderophile elements. As can be seen from Table 4, no moderately siderophile element other than Mo is affected, even though W and P are clearly depleted relative to Co and Ni in the present mantle (Table 2).

The heterogeneous accretion hypothesis results in additional predictions which are inconsistent with observed elemental abundances in the Earth's upper mantle. First, the amount of metal which was extracted from the last 20% of accreting material must have been trivial, and the high $f_{\rm O_2}$ requires that that metal must have been Ni-rich (because of the decreased stability of Fe-rich metal). If we assume that as much as 10% of the total Ni was removed during the last core-forming event (consistent with the approximately chondritic Co/Ni ratio of the upper mantle), then only 0.02% metal was removed. It would

seem that a substantially molten upper mantle would be required to separate this minute amount of metal, and, as we have already discussed, there is no evidence for a pervasive terrestrial magma ocean. Second, if the last 20% of accreted material was sufficiently oxidized to effectively halt core formation, it is expected that this material would have been enriched in volatile elements and oxidized species. If the last dregs of core formation removed only a few hundredths of a per cent of metal, it is not possible for substantial amounts of S to have been taken to the core (S is cosmically more abundant than Ni). All chondritic materials contain 2-6 wt% S. If the material which made up the last 20% of the Earth's accretion even approached chondritic composition, we would expect that the crust and upper mantle would contain 4,000-12,000 p.p.m. S: not appreciably different from the prediction of the inefficient core formation hypothesis, and in contradiction to observed S abundances of <300 p.p.m. in the Earth's upper mantle¹⁹.

In this context we note that Morgan³³ has refined his abundance estimates of incompatible noble siderophile elements (for example, Au and Re) in spinel lherzolites, and finds that the noble element ratios are remarkably chondritic. Obviously, this observation strengthens the arguments for a 1% chondritic 'latestage veneer'. Furthermore, Morgan shows that the S/Se ratio of spinel lherzolites is chondritic and advocates that the S and Se abundances of the upper mantle were established by the same 'late-stage veneer' process. The implication of Morgan's work appears to be that, before the last 1% of accretion, the mantle was sulphur-free. In principle, this may remove some of the difficulties with S which were discussed above, although it is still unclear whether such low S abundances during the last 20% of the Earth's inhomogeneous accretion are compatible with the more oxidizing conditions postulated for this stage of accretion9.

We note that the consistency of the siderophile element abundances inferred from basalts, spinel lherzolites and garnet lherzolites implies that the siderophile elements of the upper mantle are likely to be homogeneously distributed to a depth of at least 500 km—a scale consistent with models of upper mantle convection³⁴. If 1% of the mass of the upper mantle were added by a uniform flux of planetesimals and if this same population were responsible for the production of a 2.5-km megaregolith on the Moon²⁴, we would expect that the lunar megaregolith would contain ~200% of chondritic material—a physically impossible value which is about two orders of magnitude higher than the ~1.5 wt% of meteoritic material measured in lunar soils²⁴. The Moon would have to be well-mixed to a depth of 400 km in order to be consistent with the terrestrial 'late-stage veneer', yet estimates of mantle abundances of noble siderophile elements¹³ show no evidence of such mixing. Of course, it is possible that the Moon formed after the Earth accreted its final 1% of mass, although available isotopic evidence points to comparable ages for both objects35.

Although we find some elements of the heterogeneous accretion/'chondritic veneer' hypothesis attractive, this hypothesis contains as many quantitative difficulties as the inefficient core formation and metallic liquid/silicate equilibrium core formation hypotheses. It is not clear to us which, if any model of core formation should be preferred.

Conclusions

The preceding discussion emphasizes that none of the current hypotheses of core formation in the Earth survives quantitative scrutiny. For any of the hypotheses to be correct, our present knowledge of the relevant relative partition coefficients must be accurate to perhaps no better than a factor of two. We emphasize that the volume of $(P-T-f_{O_2})$ space which has been investigated in our partitioning studies (as well as those of others) is small and should be extended.

This failure of all hypotheses to quantitatively model core formation and siderophile and chalcophile element abundances in the upper mantle is disappointing, in that a detailed picture of the history of the early Earth is important to our understanding of many consequential issues, such as the origin of the Moon and the subsequent geological evolution of the Earth. What, if any, statements about core formation may be made with such confidence that they will go unchallenged?

Lack of equilibration between core and upper mantle. All viable models for the explanation of the high abundances of siderophile and chalcophile elements in the mantle implicitly assume that the core and upper mantle have not communicated over geological time. An immediate consequence of this assumption is that either convection in the mantle is layered and the upper and lower mantles communicate only with great difficulty, or the mantle which we sample today was incorporated into the subcontinental lithosphere extremely early. In fact, these two possibilities are not mutually exclusive; in any case the upper mantle and core have not equilibrated since the last addition of siderophile elements to the upper mantle.

Antiquity of siderophile and chalcophile elements in the upper mantle. However the abundances of siderophile and chalcophile elements were established, they are unlikely to have changed over geological time. Evidence from basalts indicates that the Co, Fe and Ni contents of the upper mantle have not changed since 3,500 Myr (ref. 31) and that 'future leads' cannot be explained in terms of continuous core formation³⁶. Siderophile and chalcophile element concentrations in the upper mantle were established early in the history of the Earth and are not the result of secondary processes.

The redox state of the early Earth. All models of core formation seem to require that the mantle has become more oxidized over geological time. If the FeO content of the upper mantle is the result of equilibration with metal, then the consistent FeO content of 8-10 wt% in fertile mantle nodules appears to limit the oxidation state of the early Earth to oxygen fugacities less than ~1.5-2.0 log units below the QFI buffer. (For a discussion of the assumptions involved in this calculation see ref. 37.) This estimate should be accurate and is tantalizingly close to the oxygen fugacity of the metal-olivine-pyroxene reaction of ref. 38. If the FeO content of the mantle was not established by reaction with metal but, rather, by later admixture of FeO-rich material, then the calculated oxygen fugacity is an upper limit to that obtaining during core formation. If the FeO content of the mantle was due primarily to reaction with a metallic liquid, rich in non-metals⁸, the oxygen fugacity was probably still within two log units of IW. In all these cases the mantle was once very reduced and its oxygen fugacity must have changed over geological time to its present oxidized state (that is, from near IW (or lower) to QFM; ref. 39). If the oxygen fugacity calculated at the beginning of this section is accurate, no reactions other than the Fe metal-olivine-pyroxene reaction³⁸ need be postulated; if the calculation is only an upper limit, it may be necessary to consider seriously the hypothesis that the Earth is predominantly made of enstatite-chondrite-like material.

Also, we note that the moderately low non-metal concentrations (8-12%) inferred for the core (compared with the high concentrations (~30%) of S and O in the metallic liquid of Brett⁸) appear to require that models of core formation which postulate large amounts of Fe-S-O-rich liquids cannot apply throughout the core formation process. If non-metal-rich metallic liquids contributed significantly to core formation, then additional metal, containing little or no S or O, is required to account for the observed non-metal concentrations in the present core. The easiest means of achieving such a dichotomy is probably through inhomogeneous accretion, in which earlier core-forming events were S-O-poor and later events were S-O-rich. Thus, even models which postulate oxidizing conditions for core formation may require that the oxygen fugacity changed during planetary accretion and core formation, becoming more oxidizing with time.

Future directions. We emphasize again that only a very small

volume of (P, T, f_{O_2}) -space relevant to core formation has been investigated. Two obvious areas for new experimental explorations are those of high pressure and higher oxygen fugacity. For example, from our work on iron meteorites⁴⁰, we have gained example, from our work on iron meteorites⁴⁰, we have gained some insight into the possible role of pressure. Many siderophile trace element-non-metal interactions in metallic liquids appear to be explicable in terms of a simple non-metal-avoidance model. Siderophile trace element-sulphur interactions are often ~10 times stronger than Fe-S interactions, which are known to be pressure-sensitive. (Specifically, the composition of the eutectic point in the Fe-FeS binary system becomes more Fe-rich as

pressure increases²⁷.) Extrapolating from the Fe-S system, it is possible that siderophile element-non-metal interactions will be strong functions of pressure. Quantitatively successful models of core formation may require accurate and detailed assessments of the (P, T) state of the early Earth.

ARTICLES

Binding of a specific ligand inhibits import of a purified precursor protein into mitochondria

Martin Eilers & Gottfried Schatz

Biocenter, University of Basel, CH-4056 Basel, Switzerland

Methotrexate, a folate antagonist, blocks import into mitochondria of mouse dihydrofolate reductase fused to a mitochondrial presequence. Methotrexate does not mask the presequence, but stabilizes the dihydrofolate reductase moiety. It does not inhibit import of the authentic precursor from which the presequence is derived. This suggests that dihydrofolate reductase must at least partly unfold in order to be transported across mitochondrial membranes.

TRANSLOCATION of proteins across biological membranes is a key step in the intracellular sorting and secretion of proteins. Although much is known about protein movement across various membrane systems¹, it is unclear how hydrophilic, charged proteins translocate through the hydrophobic core of a phos-

pholipid bilayer. In particular, it remains unanswered whether a protein must unfold during the transport process² or whether it can translocate in a folded state³, perhaps through transient non-bilayer domains in the target membrane⁴. We have approached this question by fusing the presequence of an im-

Fig. 1 Expression and purification of mouse DHFR carrying a mitochondrial presequence. The fusion gene encoding the first 22 residues of the yeast cytochrome oxidase subunit IV presequence linked to mouse DHFR5 was excised from the yeast-E. coli shuttle vector pLGS-D5pCoxIV-DHFR6 with BamHI and treated with Bal31 to remove flanking sequences. The ends were filled-in with the large (Klenow) fragment of E. coli DNA polymerase and the shortened fusion gene was cut with HindIII at its 3' end. A fragment of the expected size was isolated?00 and cloned into a 'TAC'-expression vector²¹ (pKK 223-3; Pharmacia) using a filled-in EcoRI site at one end and a HindIII site at the other. E. coli HB101 (ref. 22) transformants resistant to antifolates (500 μg trimethoprim ml⁻¹ or 5-10 μg 1,3-diamino-7-benzylpyrrolo-[3,2/f]quinazoline ml⁻¹) were screened by colony immunoblotting²³ using a polyclonal antiserum against mouse DHFR. Plasmid pKK-pCoxIV-DHFR (a) was isolated from a transformant giving a strong signal with the anti-mouse DHFR antibody. P_{TAC}, TAC-promoter; rrnB, ribosomal transcription terminator; Amp^r, \(\beta\)-lactamase gene. The insert shows the first 29 amino acids of the fusion protein, consisting of 22 amino acids of the subunit IV presequence (1-22), 6 amino acids introduced by the cloning procedure (I-IV) and the first methionine of mouse DHFR. E. coli transformed with plasmid pKK-pCoxIV-DHFR were grown to the late logarithmic phase on LB medium²⁴, induced for 2 h at 37 °C with 1 mM isopropyl- β -thiogalactoside, and harvested. In these induced cells, the fusion protein represented ~1% of the total cellular protein. All subsequent steps were performed at 0-5 °C. The cells were osmotically shocked to release most of the periplasmic contents25, then suspended in 250 mM KCl, 20 mM KP, pH 8.0, 1 mM EDTA, 1 mM EGTA and 0.1 mM phenylmethylsulphonyl fluoride (PMSF). The shocked cells were gently lysed by adding lysozyme to 0.4 mg ml⁻¹ and, after 30 min, octyl-polyoxyethylene (given by Dr J. Rosenbusch, Biocenter) to 1%. The lysate was diluted 10-fold with 20 mM KP_i pH 7.0, 1 mM EDTA, 0.1 mM PMSF, mixed with 0.1 vol. of 2% protamine sulphate, stirred for 15 min, and centrifuged at 6,000g for 10 min. The supernatant was chromatographed on a CM-cellulose column in the presence of 0.5% octyl-polyoxyethylene, 0.1 mM PMSF, using a linear KCl gradient (25-500 mM). Fractions exhibiting DHFR activity²⁶ were pooled, dialysed overnight against 20 mM KP, pH 5.8, and subjected to affinity chromatography on methotrexate-Sepharose⁸, using 4.5 mM dihydrofolate in 1 M KCl, 20 mM KP, pH 8.0, as eluent. b, A silver-stained²⁷ SDS/12% polyacrylamide gel. Lanes 1 and 5, authentic mouse DHFR; 2-4, purified fusion protein (36, 108 and 360 ng, respectively). Protein was assayed as described elsewhere⁵.

ported mitochondrial protein to mouse dihydrofolate reductase (DHFR)⁵, and studying the translocation of the fusion protein into isolated yeast mitochondria.

The fusion protein

Hurt et al.^{5,6} have fused the first 22 residues of the presequence of yeast cytochrome oxidase subunit IV (an imported mitochondrial protein) to the N-terminus of mouse DHFR (a cytosolic protein), and shown that the resulting fusion protein is imported and proteolytically processed by isolated yeast mitochondria or by mitochondria in living yeast cells. DHFR lacking an attached presequence is not imported. In all properties studied, import of the fusion protein into mitochondria resembled import of authentic mitochondrial precursor proteins.

When we expressed the fusion protein in *Escherichia coli* (Fig. 1a), the bacterial cells became resistant to high levels of the folate antagonists trimethoprim and 1,3-diamino-7-benzyl-pyrrolo-[3,2/f]-quinazoline, indicative of elevated intracellular levels of DHFR. When the cells were rapidly lysed in NaOH and analysed by immune blotting with antiserum against mouse DHFR, only undegraded fusion protein was detected (not shown); thus, this protein is enzymatically active *in vivo*.

The fusion protein was purified from the *E. coli* transformants by cation-exchange chromatography in the presence of a nonionic detergent, followed by affinity chromatography on Sepharose derivatized with the folate antagonist methotrexate⁸. The purified fusion protein was nearly homogeneous as judged by SDS-polyacrylamide gel electrophoresis (Fig. 1b); by this procedure, 1 litre of an *E. coli* culture harvested in late logarithmic phase yielded 180 µg of purified fusion protein.

The fusion protein appeared to aggregate within the *E. coli* cells and required detergent for efficient extraction (not shown). Once extracted, however, it remained soluble even on removal of the detergent. The purified soluble fusion protein exhibited

DHFR activity; its specific activity (13 U mg⁻¹) was lower than that of authentic mouse DHFR (31 U mg⁻¹) but the fusion protein might have retained traces of methotrexate that had leaked off the affinity column. The $K_{\rm m}$ values for NADPH were 0.58 μ M for the fusion protein and 0.54 μ M for authentic DHFR. For technical reasons, $K_{\rm m}$ values for dihydrofolate could not be measured precisely, but they, too, were similar (0.13-0.31 μ M).

We conclude that the attachment of a presequence to the amino-terminus of DHFR does not significantly alter the protein's enzymatic properties, and therefore probably does not greatly alter the protein's conformation: the presequence and attached 'mature' sequence probably represent separate domains. The experiments reported below support this view.

Blockade of fusion protein import

The purified fusion protein was imported by energized yeast mitochondria (Fig. 2a). When 35 ng of purified fusion protein was incubated with 120 µg of de-energized yeast mitochondria, 7 ng (20%) was found in association with the mitochondria (Fig. 2a, lane 2) but was not imported: it remained accessible to externally added proteinase K (lane 3). On incubation with energized mitochondria, however, 42% (15 ng protein) of the fusion protein molecules were imported: they were cleaved to a smaller species (Fig. 2a, lane 4) which was inaccessible to externally added protease (lane 5). When the mitochondrial membranes were disrupted with detergent, the imported molecules, too, became accessible to added protease; under these conditions, they were cleaved to a proteolytic fragment (Fig. 2a, lane 6) distinctly smaller than that generated on import into mitochondria (compare lanes 5 and 6). Methotrexate (55 nM) inhibited mitochondrial import of the fusion protein by 89%; binding to the mitochondrial surface was decreased by only 17% (Fig. 2b; all lanes correspond to those of Fig. 2a

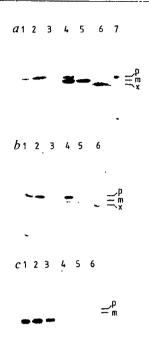

Fig. 2 Methotrexate blocks import of the fusion protein into isolated mitchondria. a, Lanes 1 and 7, 3.5 ng fusion protein (10% of the amount added to mitochondria); 2 and 3, fusion protein incubated with de-energized mitochondria (1 µg valinomycin ml was present); 4-6, fusion protein incubated with energized mitochondria. The samples shown in lanes 3 and 5 had been treated with proteinase K after import; that in lane 6 had been treated with proteinase K in the presence of 1% Triton X-100. p and m, uncleaved and cleaved fusion protein, respectively; x, proteaseresistant degradation product of DHFR. Relative molecular masses (M_rs) were 25,000 (25K), 22K and 21K for p, m and x, respectively. b, Same as a, except that all incubations contained 55 nM methotrexate, and lane 7 was omitted. c, Import of the fusion protein into energized mitochondria in the presence of the following concentrations (nM) of methotrexate: lane 1, 0.83; 2, 2.75; 3, 8.3; 4, 27.5; 5, 83; 6, 275. Import conditions as in a, lane 5. Methods. E. coli transformed with pKK-pCoxIV-DHFR were pulse-labelled for 30 min at 37 °C with 2 mCi of carrier-free 35 SO₄ (>1,000 Ci mmol⁻¹) in synthetic minimal medium supplemented with 1 mM isopropyl- β -D-thiogalactoside and all amino acids except cysteine and methionine²⁸. The fusion protein was then isolated as described in Fig. 1 legend except that affinity chromatography was omitted. Fractions eluted from CM-cellulose were analysed for fusion proteins by SDS-polyacrylamide gel electrophoresis and fluorography. Appropriate fractions were pooled and dialysed overnight against 100 mM KCl, 20 mM HEPES-KOH pH 7.4, 1 mM EDTA, 1 mM dithiothreiol, 0.1 mM PMSF. Aliquots of the purified fusion protein (35 ng; 1.5×10° c.p.m. per mg protein) were incubated with isolated yeast mitochondria (120 µg protein) for 30 min at 30 °C and the mitochondria were analysed for imported fusion protein²⁹. Internalization was ascertained by treating the re-isolated mitochondria with 50 µg proteinase K (250 µg ml⁻¹) for 30 min at 0 °C before electrophoretic analysis. The amount of added fusion protein was quantitative by calibrated immune blotting6, using authentic mouse DHFR as a standard.

except that methotrexate was added to all incubations). Methotrexate inhibited import of the fusion protein at roughly the same concentration at which it inhibited the enzymatic activity of pure mouse DHFR (Fig. 2c), the $K_{\rm m}$ values for inhibition of import and of enzymatic activity being 4.1 and 3.8 nM, respectively (data not shown). The result suggests that methotrexate blocks mitochondrial import of the fusion protein by binding to the catalytic syte? on DHFR.

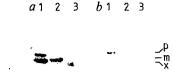

Fig. 3 A hydrophobic folate antagonist also blocks import of the fusion protein into yeast mitochondria. All incubations were carried out as described in Fig. 2 legend. a, Lanes 1, 2 and 3 show, respectively, fusion protein incubated with energized mitochondria and left untreated, treated with proteinase K or treated with proteinase K in the presence of 1% Triton X-100. b, Same as a, except that all incubations contained 1 μ M 1,3-diamino-7-benzylpyrrolo-[3,2/f]-quinazoline.

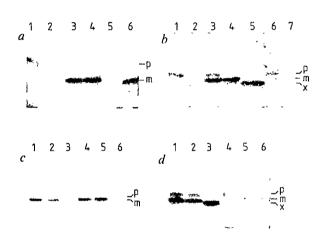

Fig. 4 Methotrexate only inhibits mitochondrial import of fusion proteins containing DHFR. All proteins tested for import were synthesized by coupled transcription/translation14 in the presence of 35S-methionine. Import into isolated yeast mitochondria was assayed as described in Fig. 2 legend. a, Authentic precursor to yeast cytochrome oxidase subunit IV. Lane 1, de-energized mitochondria; 2, de-energized mitochondria, plus protease; 3-5, energized mitochondria left untreated, treated with protease, or treated with protease and 1% Triton X-100, respectively; 6, energized mitochondria in the presence of 250 nM methotrexate, followed by protease treatment. For p, m and x, see Fig. 2. p, 17K; m, 14K. b, Fusion protein containing the first 22 residues of the subunit IV presequence attached to mouse DHFR. Lanes 1-5, analogous to those of a; 6, energized mitochondria plus 50 nM methotrexate; 7, energized mitochondria, protease treatment, plus 50 nM methotrexate. p, 25K; m, 22K; x, 21K. c, Authentic precursor to the yeast mitochondrial isozyme alcohol dehydrogenase III. Lanes 1-3, no methotrexate; 4-6, plus 15 nM methotrexate; 1 and 4, energized mitochondria; 2 and 5, energized mitochondria, protease-treated; 3 and 6, energized mitochondria, protease-treated, plus Triton X-100. p, 40K; m, 37K. d, Fusion protein containing the first 27 residues of the alcohol dehydrogenase III precursor attached to mouse DHFR. Lanes correspond to those of c. p, 25K; m, 22K; x, 21K.

Import of the purified fusion protein into mitochondria is also blocked by 1,3-diamino-7-benzylpyrrolo-[3,2/f]-quinazoline, a membrane-permeant antifolate (ref. 10 and R.L. Then, personal communication) (Fig. 3). The inhibition of import of the fusion protein is, therefore, not simply a consequence of the inability of methotrexate to cross biological membranes.

To demonstrate that methotrexate is not a general inhibitor of mitochondrial protein import, we tested its effect on

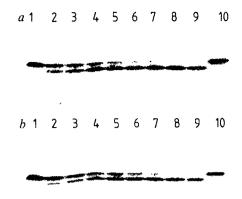

Fig. 5 Methotrexate does not inhibit the action of mitochondrial processing protease on the presequence attached to DHFR. a, Lane 1, no incubation with protease; lanes 2-9, incubation with protease for 1.5, 2.5, 5, 7.5, 10, 15, 20 and 30 min, respectively; lane 10, incubation for 30 min in the presence of 1 mM 1,10-phenanthroline, a relatively specific inhibitor of the matrix protease. b, Same as a, except that all incubations contained, in addition, 70 nM methotrexate.

Methods. The fusion protein containing the first 22 residues of the subunit IV presequence attached to mouse DHFR was synthesized in vitro in the presence of ³⁵S-methionine (see Fig. 4 legend) and incubated with the partially purified ¹⁵ processing protease. Samples were precipitated with 5% trichloroacetic acid and analysed by SDS/12% polyacrylamide gel electrophoresis and fluorography.

mitochondrial import of four different proteins: (1) the authentic precursor to cytochrome oxidase subunit IV¹¹; (2) the authentic precursor to yeast alcohol dehydrogenase III (a mitochondrial isozyme¹²); (3) mouse DHFR linked to the first 22 residues of the cytochrome oxidase subunit IV presequence⁵ (that is, the fusion protein described above); and (4) mouse DHFR linked to the first 27 residues of the alcohol dehydrogenase III precursor¹³. Each of the four proteins was synthesized in vitro by coupled transcription-translation in the presence of 35Smethionine and tested for cleavage and import by isolated yeast mitochondria. Methotrexate blocked import of only the two fusion proteins (Fig. 4b, d); it did not measurably affect import of the two authentic precursors whose presequences had been used to construct the fusion proteins (Fig. 4a, c). Thus, methotrexate blocked mitochondrial import of only those proteins containing a DHFR moiety.

Methotrexate binding

Binding of methotrexate to the fusion proteins could trigger an interaction between the DHFR domain and the attached presequence, rendering that presequence inaccessible to the mitochondrial import machinery. Two observations make this possibility unlikely. First, methotrexate did not significantly affect binding of the fusion proteins to de-energized mitochondria (Figs 2, 4); as DHFR lacking a presequence does not bind to mitochondria14, binding of the fusion proteins shows that the presequence is accessible. Second, methotrexate did not significantly inhibit removal of the attached presequence by the processing protease partially purified15 from the yeast mitochondrial matrix (Fig. 5). Methotrexate did, however, partially protect the DHFR moiety against degradation by low concentrations of thermolysin (Fig. 6). Incubation of the purified fusion protein with thermolysin in the presence of methotrexate caused accumulation of a degradation intermediate whose size corresponded to that of DHFR lacking a presequence (Fig. 6, lanes 5-11). Methotrexate also protected authentic DHFR against thermolysin; in that case, however, no smaller intermediate was detected (not shown). Thus, it is likely that the cleaved-off

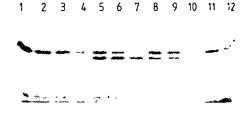

Fig. 6 Methotrexate protects DHFR against degradation by thermolysin. ³⁵S-labelled purified fusion protein (7.5 ng; see Fig. 1 legend) was incubated for 30 min at 43 °C in 0.1 M HEPES-KOH pH 7.4, 2 mM CaCl₂ in the absence of protease (lane 1) or with 5.6 ng (lanes 2, 5, 8, 11), 11.2 ng (lanes 3, 6, 9, 12) or 28 ng (lanes 4, 7, 10) of thermolysin, either in the absence of methotrexate (lanes 1-4), or in the presence of 16.5 μM (lanes 5-7), 660 nM (lanes 8-10) or 66 nM (lanes 11, 12) methotrexate. The final volume in each case was 50 μl. Samples were then mixed with 5 μl of 0.2 M EGTA and analysed by SDS/12% polyacrylamide gel electrophoresis and fluorography.

fragment which is not protected from thermolysin by methotrexate is indeed the presequence. Control experiments (not shown) established that methotrexate at a concentration as high as $7 \mu M$ did not affect the action of thermolysin on yeast hexokinase or chicken ovalbumin.

Implications for protein translocation

How does methotrexate block import of the DHFR-containing fusion proteins into mitochondria? We can exclude the possibility that it blocks mitochondrial protein import per se or causes masking of the presequence. Amost certainly, it also does not induce a major structural change in the DHFR moiety: extensive X-ray crystallographic studies on the interaction between chicken DHFR and antifolates have revealed only a minor displacement of Tyr 30 and Glu 31 (refs 9, 16). These data should also apply to mouse DHFR as the amino-acid sequences of the two enzymes show 77% homology 17,18. Such extensive sequence homology predicates close resemblance of the three-dimensional structures?

It could be argued that methotrexate by itself might not be able to pass membranes and thereby might block translocation of any protein to which it is bound. This possibility is rendered highly unlikely by the finding that 1,3-diamino-7-benzylpyrrolo-[3,2/f]-quinazoline also blocks import of the purified fusion protein; this folate antagonist is uncharged and highly hydrophobic and has been shown to pass freely through cell membranes of yeast¹⁰ and E. coli (R.L. Then, personal communication).

The combined evidence strongly suggests that folate antagonists block the translocation of DHFR through mitochondrial membranes by preventing unfolding of the protein. This view is in accord with the crystallographic evidence on the interaction between antifolates and DHFR and the protection data described here. By binding tightly to DHFR, antifolates impede unfolding of the enzyme. In line with this interpretation is the recent observation of a translocation intermediate during the import of the precursors of the F_1 -ATPase β -subunit and cytochrome c_1 into Neurospora mitochondria¹⁹. This intermediate accumulated at low temperature and appeared to span both mitochondrial membranes, as it remained accessible to an externally added protease even though the presequence had already been cleaved off by the matrix-located processing protease. To allow such an orientation, at least the amino-terminal portion of the imported proteins must have been partially unfolded. Neither of these observations, however, give any indication as to how extensive the unfolding must be to allow movement of the protein across a membrane. The purified, translocationcompetent fusion protein described here should be a valuable tool for investigating this question.

This study was supported by grants 3.394-0.83 and 3.660-0.84 from the Swiss NSF. We thank Dr J. Kraut (University of California, San Diego) for sending us the unpublished crystallographic coordinates of chicken DHFR; Drs R. L. Then and D.

Stüber (Hoffman-La Roche Co., Basel) for gifts of antifolates and mouse DHFR, respectively; Dr E. Mehler (Biocenter, Basel) for valuable advice; W. Oppliger for technical assistance; and M. Probst and L. Schwörer for typing the manuscript.

Observations of velocity waves from the 5-min p-mode oscillations in the solar sub-photospheric cavity have permitted a number of important inferences about physical conditions and differential rotation in the solar interior¹. Models also predict the existence of an overlying acoustic cavity, defined by reflections between the temperature minimum and the sharp rise from chromospheric to coronal temperatures²⁻⁵. Observations of chromospheric emission features^{6,7}, the cores of strong absorption lines⁸⁻¹¹ and the farinfrared continuum¹² have established that chromospheric oscillatory power is shifted to higher frequencies than is the case for the sub-photospheric cavity. However, it remains to be established that this oscillatory power is sufficiently localized to indicate the presence of resonant modes at frequencies close to the predicted eigenfrequencies. We have obtained time-series observations of an infrared (11-µm) solar OH absorption line profile, on two consecutive days, using a laser heterodyne spectrometer to view a 2-arc-s portion of the quiet Sun at disk centre. A power spectrum of the line-centre velocity shows the well-known photospheric p-mode oscillations very prominently, but also shows a second feature near 4.3 mHz. A power spectrum of the line intensity shows only the 4.3-mHz feature, which we identify as the fundamental (n = 1)p-mode resonance of the solar chromosphere. The frequency of the mode is observed to be in substantial agreement with the eigenfrequency of current chromospheric models. A time series of two beam difference measurements shows that the mode is present only for horizontal wavelengths >19 Mm. The period of a chromospheric p-mode resonance is directly related to the sound travel time across the chromosphere, which depends on the chromospheric temperature and geometric height. Thus, detection of this resonance will provide an important new constraint on chromospheric models.

Frequency difference (MHz)

Fig. 1 Sample line profiles obtained on 16 June 1985 in three consecutive integrations, showing changes in the solar line profile and stability in the PH₃ gas-cell line. LO, local oscillator (13C16O₂ P(12), 903.74974 cm⁻¹); OH, R22(27.5)f rotational transition of OH, PH₃, phosphine absorption feature.

We measured the Doppler shift and line intensity of a 903.769cm⁻¹ (11.065-µm) OH absorption feature with a 2-arc-s field of view (full width at half-maximum, FWHM) centred on the solar disk, and not following the solar rotation. We used the Goddard laser heterodyne spectrometer at the McMath telescope of the National Solar Observatory, in June 1985. The design and operation of the instrument are discussed in ref. 13. The R22(27.5)f rotation transition of OH was measured using a peak-power stabilized laser local oscillator operating on the I-band, P(12) transition of $^{13}C^{16}O_2$ at $903.7497\,\mathrm{cm}^{-1}$. The observations were made in the optically null-balanced mode described in ref. 14. In this mode, the instrument uses a 27-Hz mirror-chopper to alternately place the Sun and a local hightemperature black body on the detector. Line profiles are measured in the optical difference spectrum. To monitor the laser stability, an absorption cell containing phosphine (PH₃) at 0.5 torr was placed in the black-body (BB) beam. A PH₃

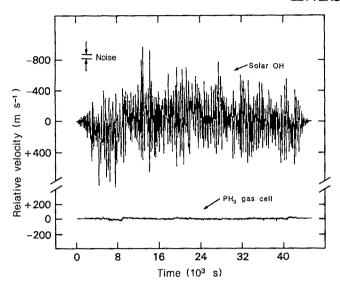

Fig. 2 Time series of line-centre velocity for the solar OH feature and PH₃ gas-cell line. The velocity scales are of opposite sense because the lines occur in opposite side bands. Both time series were apodized using a 10% cosine bell. The 1σ statistical noise level for a single solar measurement is 26 m s^{-1} and is indicated in the upper left. The corresponding 1σ level for the PH₃ line is 5 m s^{-1} .

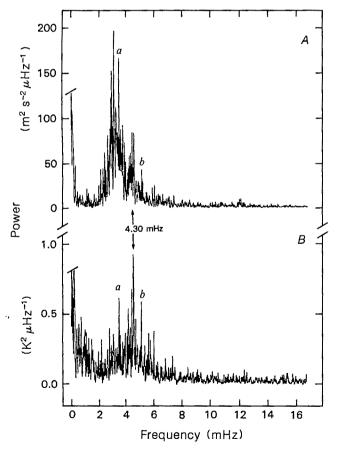

Fig. 3 Power spectra of line velocity (A) and line intensity (B), calculated from the concatenated data of 15 and 16 June, and smoothed to $20 \,\mu$ Hz resolution. The line velocity was measured in metres per second and the line depth was measured in kelvins. The peaks near zero frequency in both spectra are due to instrumental effects, and are not of solar origin. The arrows indicate the solar chromospheric mode at 4.30 mHz, and the features labelled 'a' and 'b' are discussed in the text.

absorption feature is thus recorded simultaneously with the solar OH feature in each 30-s integration. In Fig. 1, three consecutive integrations show the solar OH feature near the centre, and the PH₃ feature near 1,450 MHz. The PH₃ line appears inverted because each result is obtained as a difference spectrum (Sun-BB). A gaussian profile is fitted to each line to determine the line centre position, and line intensity (depth) relative to the continuum. It is evident from Fig. 1 that the solar line shows large fluctuations in both line centre frequency and line intensity. These fluctuations are not seen in the PH₃ gas-cell line, indicating that potential instabilities in the local oscillator frequency are negligible.

Our Sun-centre time series spanned a total of 2 days (15-16 June), with a total of 18.7 h of data. Figure 2 shows apodized velocity time series for 16 June. The results of the PH2 profile fitting are displayed below the solar results to show the overall instrument stability. The solar time series shows r.m.s. (rootmean-square) velocity fluctuations of ~300 m s⁻¹, greatly in excess of the $26 \,\mathrm{m \, s^{-1}}$ (1 σ) error associated with a single measurement. The only instrumental effect which is noticeable in Fig. 2 is represented by a slow drift in both time series, which is corrected near 8,600 s. This is caused by changes in the spectral baseline due to changes in the detector response. The leastsquares algorithms which compute the line shape parameters cannot fully compensate for these baseline drifts, because the bandpass of the heterodyne spectrometer is so narrow. However this instrumental effect has no impact for the present purpose, because it propagates into the power spectra only at the lowest frequencies.

Velocity and line intensity power spectra from both days of observations were calculated using the method of Deeming¹: the velocity spectrum is shown in Fig. 3A. The spectrum of the concatenated data has been smoothed to a resolution of 20 µHz (FWHM) to suppress the side-lobes produced by the night-time data gap. We checked the extent of side-lobe contamination by calculating power spectra of continuous sine waves with the same data sampling. The velocity spectrum shows the dominant 3-mHz band from the subphotospheric cavity. Individual modes in this band cannot be distinguished because of the lack of spatial wavenumber resolution. The second most prominent feature is the relatively narrow band of power near 4.3 mHz, which we identify as a chromospheric resonance. The integrated power in the range 3.86-4.47 mHz produces an r.m.s velocity amplitude of 50 m s⁻¹. This is too large to be attributed to instrumental drifts or solar image motion at this frequency. The reality of the 4.3-mHz feature is confirmed in Fig. 3B, which shows the power spectrum of the line depth. In this figure the photospheric p-modes are essentially absent; only the 4.3-mHz feature is evident. The central peak in this spectrum occurs at 4.30 ± 0.01 mHz, in very close agreement with the locus of frequencies predicted by Ando and Osaki³ for radial order n = 1. Two other peaks, labelled 'a' and 'b', are also prominent in both spectra at identical frequencies. They occur at 3.39 mHz (a) and 4.96 mHz (b). Although they do not correspond to overtones of higher radial order (n>1), we speculate that they may represent resonances due to different components in an inhomogeneous chromosphere.

Several factors lend confidence to our identification of the n=1 chromospheric resonance. (1) Our infrared observations sample the upper photosphere, where the chromospheric mode becomes increasingly prominent relative to the photospheric mode¹⁶. (2) The mode is observed at a frequency in close agreement with the predicted eigenfrequency. (3) The mode is clearly present in power spectra of the line intensity as well as the line velocity. It is distinguished from the photospheric pmodes by being relatively more prominent in the line intensity spectrum. This is expected, as the temperature perturbation associated with the chromospheric mode will be less affected by radiative damping¹⁷. (4) Compared with many previous chromospheric observations, our data are of relatively long

duration, making our result more representative of average conditions in the upper solar atmosphere. (5) The lack of solar activity at the time of our observations provided optimum conditions for the existence of a resonance.

In addition to the power spectra of Fig. 3, we have also examined power spectra from a 1-day sequence of dispersionline shapes, obtained on 18 June 1985 by chopping our 2-arc-s field of view between two locations on the solar disk separated by 26 arc s (see ref. 13). These data allow us to derive the velocity and line intensity difference between these two locations, and power spectra of these quantities show no evidence of the chromospheric mode. This implies that the mode is being coherently subtracted in these data; therefore, its horizontal wavelength must exceed the 19-Mm chopping distance. A long horizontal wavelength for this mode is also consistent with the low-spatial-resolution data of Lindsey and Kaminski¹², provided that we identify the chromospheric mode as producing the 3-6-mHz oscillatory power which they observed in the intensity

Shape memory behaviour in partially stabilized zirconia ceramics

M. V. Swain

CSIRO Division of Materials Science, Locked Bag 33, Normanby Road, Clayton, Victoria 3168, Australia

Shape memory behaviour has been observed in a variety of metallic alloys. It is usually associated with specific materials which on being deformed to various degrees of inelastic strain, return to their original shape on heating. The essential requirement is that they undergo reversible martensitic (diffusionless) phase transformations on heating and cooling. The past decade has seen considerable scientific and technological interest in ceramics containing zirconia (ZrO₂), a material that exhibits such martensitic transformations. This interest has arisen because of the high strengths and toughness that can be achieved in such materials by a stress-induced volume-expanding phase transformation about the crack tip1. Observations are reported here of shape memory behaviour in a zirconia alloy partially stabilized with magnesia, at temperatures a few hundred degrees higher than reported for metallic alloys. The reversible deformation strains are relatively small, 0.5%, and are limited by the brittleness of the ceramic material. In the MgO-PSZ material the phase exhibiting the martensitic behaviour is the minor phase and occurs as precipitates in a stable

In the course of thermal cyclic testing of magnesia-partiallystabilized-zirconia (MgO-PSZ) material (J. E. Excel, M. Marmach and M. V. S., unpublished results) a behaviour very similar to the so-called shape memory effects of certain metallic alloys was observed. Shape memory behaviour was first observed about 40 years ago in various metallic alloys, and has since found technological applications². The metallic alloys based on compositions containing NiTi or CuAlNi have attracted much interest. The copper-containing alloy has created interest recently through an attempt to increase the temperature at which the deformation remains reversible³.

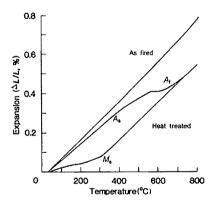

Fig. 1 Thermal expansion curves for the as-fired and heat-treated MgO-PSZ.

The essential requirement for shape memory alloys is that they undergo reversible martensitic phase transformations on heating and cooling, and this usually also means that the twin boundaries of the lower-symmetry (lower-temperature) phase must be sufficiently mobile or glissile to enable reorientation on the application of stress. The twin boundaries within the lowtemperature phase must then consist of partially or fully coherent interfaces, to enable reversal on heating. Deformation of the alloy under load usually takes place below the martensitic start temperature, M_s , with non-linear strain being accommodated by the reorientation of the twin laths within the microstructure. It is also possible to achieve such non-linear strain above M_s but below a specific temperature, M_d , by a stress-induced transformation. On heating materials that have been deformed in either manner to above the $A_{\rm f}$ temperature, where the lowertemperature crystal structure completely reverts back to the high-temperature phase, the bodies return to their original prestrained states. The reversal of the deformation begins at the temperature at which the reverse martensitic phase change starts, A_s , and is complete at A_f . Shape memory behaviour has usually been described for metals where the entire alloy is single phase, although some data exist for NiTi alloys containing minor volume fractions of intermetallic precipitates².

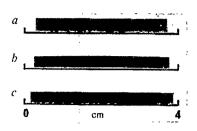

Fig. 2 Optical micrographs of the as-fired (a) and heat-treated (b) material after thermal cycling to 800 °C under a flexural stress of 200 MPa. c, Thermal cycling of a deformed bar to 800 °C in the absence of stress leads to the near complete reversal of the deflection.

PSZ ceramics are a new class of strong and tough materials that may be fabricated to use a martensitic transformation to increase their toughness1. The tetragonal phase of zirconia undergoes a martensitic transformation to monoclinic zirconia, accompanied by a 4-6% volume dilation and 9% shear strain. The temperature at which this transformation takes place is dependent on the solute content, precipitate size and matrix constraint, if any, imposed on the tetragonal material. To optimize the toughness of these materials, the content and size of the tetragonal grains or precipitates is adjusted so that M_s is just below the temperature of interest. The application of tensile stresses, for example about a crack tip, can trigger the volumeexpanding transformation, leading to crack-tip shielding and a higher fracture toughness. With this mechanism a 10-fold increase in K_{1c} is achievable in optimum alloy compositions⁴. In addition to the increased toughness, recent studies have shown that the application of stress may lead to ductile behaviour due to the tetragonal to monoclinic induced transformation, and deformation strains of 0.25% have been reported5-

The present observations were noted during thermal cycling tests on MgO-PSZ alloys in four-point flexure. These materials, containing 9.4 mol % MgO, consisted of coarse grains (~50 μm) of a cubic zirconia matrix with ~35 vol. % tetragonal zirconia precipitates in the as-fired state. Some of these bars were heattreated (at 1,100 °C for 9 h) to partially destabilize the tetragonal precipitates on cooling; that is, M_s was above room temperature. Example of the thermal expansion curves of the as-fired and heat-treated materials are shown in Fig. 1. The M_f temperature of the aged material was below room temperature and the monoclinic content of the polished surface as determined from the 111 X-ray diffraction peaks⁸ was 15%. Details of the heat treatment of MgO-PSZ materials are discussed elsewhere⁹ The thermal expansion hysteresis of PSZ alloys is much larger, particularly in the temperature axis, than most metallic alloys, and has been attributed to the constrained nature of the transforming precipitates¹⁰.

Thermal cycling tests consisted of loading rectangular bars, $3 \times 4 \times 40$ mm, in a four-point flexure, dead-weight loading jig, such that the tensile stress at the outer fibre was 200 MPa. No difference in behaviour was detected between specimens that had a ground or polished surface. The inner and outer spans of the flexure jig were 15 mm and 30 mm. The bars were slowly heated at $100 \,^{\circ}\text{C}$ h⁻¹ to $800 \,^{\circ}\text{C}$ and held for 2 h before cooling at $100 \,^{\circ}\text{C}$ h⁻¹. The as-fired material on such a thermal cycle behaved as anticipated for an elastic non-creeping body, whereas the heat-treated material was quite bent after such a cycle. A comparison of the two bars after such a thermal cycle under load is shown in Fig. 2a, b. On re-heating the bent bar to $800 \,^{\circ}\text{C}$ at the same heating and cooling rates in the absence of stress, it returned almost completely to its original shape, as seen in Fig. 2c.

The permanent strain in the outer fibre of the bent bar after thermal cycling under load was calculated from the radius of

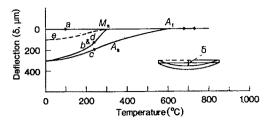

Fig. 3 A plot of the non-elastic deflection of the heat-treated material on heating and cooling under stress (corrected for thermal expansion of as-fired material). a, Heating under load (200 MPa); b, cooling under load (200 MPa); c, re-heating under load (200 MPa); d, cooling under load (200 MPa); e, cooling without load.

curvature, ρ , using the simple relationship

$$\varepsilon = t/2\rho \tag{1}$$

where t is the beam thickness. This analysis assumed that the neutral axis remains in the middle of the deformed bar. Recent studies of stress-induced transformation during flexure have shown that the neutral axis is displaced⁶, and the above estimate for the strain is slightly conservative. From equation (1) the retained deformation strain at room temperature was found to be 0.42%, which is much larger than the deformation strains (typically 0.2%) reported in peak-toughness MgO-PSZ and CeO₂-PSZ alloys loaded in tension or flexure⁵⁻⁷. The retained inelastic strain after re-heating to 800 °C and cooling to room temperature in the absence of external stress was 0.14%. The influence of applied stress on the extent of deformation strain and retained strain after re-heating in the absence of stress is being investigated and will be reported elsewhere.

To determine when the deformation was taking place, a linear variable displacement transducer (LVDT) was used to monitor the movement of the loading arm during heating and cooling. On heating and cooling the loading rams expanded and contracted substantially more than the specimen deformation. However, by subtracting the thermal expansion and contraction of the as-fired material from that of the heat-treated material it was possible to deduce the temperature at which deformation began. An additional experiment of re-heating the bent specimen under load was also performed to evaluate if, and at what temperature, the deformation reversed. The corrected deflection of the bar with temperature during heating and cooling on the first and second thermal cycles is shown in Fig. 3. Also shown are the $M_{\rm s}$, $A_{\rm s}$ and $A_{\rm f}$ temperatures determined from the thermal expansion curve in Fig. 1.

The results in Fig. 3 show that the bar begins to deform on cooling at temperatures $\leq M_s$. On re-heating under load the bar begins to return to its original shape at temperatures below A_s and the process seems to be complete by A_t . On cooling, the deformation is identical to the initial cycle at temperatures below M_s . These observations are very similar to the observations in metallic shape memory alloys. The main differences are that the temperatures at which the deformation and reversal occur are hundreds of degrees higher in the MgO-PSZ and the extent of deformation strain is much less. There appears to be a small remnant of irreversible deformation associated with reheating above A_f in the absence of stress. This behaviour is also observed in metallic alloys, which exhibit a large hysteresis between M_s and A_f (ref. 2).

Crystallographic analysis of the orientation relationships of transformed monoclinic zirconia precipitate in a cubic matrix is an area of active research. Recent detailed transmission electron microscopy (TEM) of the twinned monoclinic precipitates in MgO-PSZ has shown that 12 different crystallographic variants exist¹¹. It has also been observed that the twin orientations in the monoclinic structure could differ from precipitate to precipitate and were dictated by the local stress state.

Microcracks, observed at the interface between matrix and precipitate, accommodated lattice strains which arose, particularly at specific twin domain/interphase boundaries. More recently, Hannink et al. 12 used a technique of in situ TEM straining of almost identical MgO-PSZ alloys using electron-beam heating and subsequently annealing transformed precipitates in the same manner. They also observed that the orientation of the monoclinic twin variants of individual precipitates is dependent on the superimposed local stress state. On annealing, the precipitates revert back to their original tetragonal shape, regardless of the pre-existing twin variants. In these TEM experiments, there was no attempt to monitor the temperature of the foil and therefore determine the M_s and A_s of individual precipitate. However, some residual strain did remain after annealing, particularly at sites where microcracking was observed when the precipitate was in the twinned monoclinic form. The presence of such residual strain sites may well contribute to the destabilization of some of the associated metastable tetragonal precipitates in a preferred manner on cooling. This would lead to some residual strain after re-annealing in the absence of a biasing or superimposed stress on the body, and may account for the slight residual deflection of the beam.

The present experiments strongly support the contention that shape memory behaviour, due to a martensitic reaction, occurs in PSZ ceramics. The application of a biasing stress as the body cooled through the M_s temperature leads to a deflection of the specimen which could be almost completely removed on annealing above the $A_{\rm f}$ temperature. Although the present experiments have been carried out with MgO-PSZ alloys, it is anticipated that similar behaviour would be observed in other zirconiatoughened ceramics with the appropriate phase assemblage. [Since submitting this manuscript, shape memory behaviour has also been observed in a fine-grained yttria (Y₂O₃)-PSZ ceramic (M. Matsui and T. Soma, personal communication.] At this stage it is uncertain what contribution the volume dilation associated with the transformation makes to the deformation strain developed in cooling through M_s under load. In addition, the ability of the stiff non-transformable cubic matrix phase to absorb the large deformations during cooling and heating through M_s and A_s under load is not understood. The limited strains associated with the inelastic deflection and subsequent recovery on annealing with the investigated MgO-PSZ alloy are so small that it is too early to speculate about technological applications of such shape memory behaviour. However, the much higher temperatures at which this behaviour is being observed in PSZ materials, and the ability to vary the M_s and $A_{\rm f}$ temperatures to >1,200 °C by the addition of hafnium oxide, may provide technological opportunities unavailable for metallic shape memory alloys. The upper temperature application limit for zirconia ceramics, like metallic alloys, will be controlled by the temperature at which the internal elastic strains responsible for the shape memory effect are relaxed by thermally activated processes.

The provision of specimens by J. Excel and M. Marmach is appreciated, as are discussions with and access to unpublished work of R. H. J. Hannink, L. R. F. Rose, N. Kennon, D. Dunne and M. J. Bannister. I thank H. G. Scott and Professor A. P. Miodownik for constructive comments.

Unusual conditions in the tropical Atlantic Ocean in 1984

S. G. H. Philander

Geophysical Fluid Dynamics Laboratory/NOAA, Princeton University, Princeton, New Jersey 08542, USA

During the first half of 1984, oceanic and atmospheric conditions in the tropical Atlantic were, in many respects, similar to conditions in the Pacific Ocean during El Niño: the upper ocean was unusually warm in the eastern part of the basin, rainfall was heavy over the normally arid regions to the south of the Equator, and coastal upwelling was inhibited in regions (southwestern Africa) where this is a seasonal phenomenon. The change in sea-surface temperatures, which resulted when unusual eastward currents to the south of the Equator transported warm surface waters towards Africa, contributed to the change in atmospheric conditions. The altered atmospheric conditions, in turn, contributed to the change in the oceanic circulation and the change in the sea-surface temperature.

Figure 1 contrasts the sea-surface temperatures (SSTs) in the tropical Atlantic in June 1983 and June 1984. The higher SSTs in 1984 were associated with exceptionally heavy rainfall over northeastern Brazil and the coastal zone of southwestern Africa but were also associated with a persistence of the drought in the Sahel, the region to the south of the Sahara desert. This happened because the Intertropical Convergence Zone¹ (ITCZ), the narrow east-west band of rising air, cloudiness, and heavy rainfall onto which the south-east and north-east trades converge, was displaced unusually far southward during 1984. Such a displacement of the ITCZ is also a feature of El Niño in the Pacific Ocean. However, the other important feature of El Niño, eastward movement of the atmospheric convective zone that is normally over the western equatorial Pacific, had no counterpart in the Atlantic during 1984. In the Pacific the eastward movement of the region of heavy rainfall and low sea-level pressure, towards the arid eastern equatorial Pacific where sea-level pressure is normally high, results in negatively correlated variations in the eastern and western sides of the ocean basin. During the warm event in the Atlantic, by contrast, the increase in rainfall and decrease in sea-level pressure was fairly uniform in the east-west direction.

The dominant change in the Atlantic was not a zonal one—the low-pressure convective zone over the Amazon Basin was not dislodged from the continent-but was a meridional one associated with the equatorward movement of the ITCZ. The ITCZ is the principal region of rainfall over the tropical Atlantic Ocean and the adjacent land. Seasonally it moves between the Equator and 15 °N, approximately, so that northeastern Brazil has a rainy season in March and April when the ITCZ is furthest south, whereas the Sahel (10 °N to 15 °N in west Africa) has a rainy season centred on August when the ITCZ is furthest north. Because of this dependence on the ITCZ for rainfall, latitudinal precipitation gradients are enormous: annual mean rainfall along the west African coast is 1,939 mm at Bissau (12 °N), 542 mm at Dakar (15 °N) and 123 mm at Nouakchott (18 °N). These statistics make it clear that slight variations in the position of the ITCZ, which has a very small north-south extent, have a major effect on rainfall variations in west Africa. The unusual southerly position of the ITCZ in 1984 contributed significantly to the persistence into 1984 of the drought in the Sahel, and to the heavy rainfall and floods in northeastern Brazil and the coastal zone of equatorial and southwestern Africa, including Angola.

Atmospheric convective zones over the ocean are usually over the warmest surface waters. The ITCZ, for example, is in the neighbourhood of the Equator when SSTs in that region are at

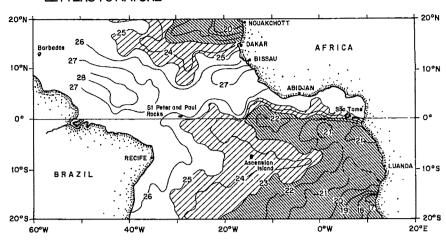

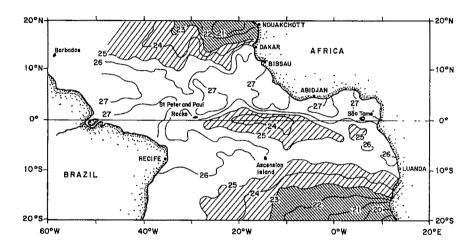

Fig. 1 Sea-surface temperatures (°C) in the tropical Atlantic Ocean in June 1983 (top) and June 1984 (bottom).

a maximum (March and April) and it moves northward when SSTs at, and to the south of the Equator in the central and eastern Atlantic start to fall. Interannually, southward displacement of the ITCZ is correlated with, and in models is effected by, an increase in SST to the south of the Equator and a simultaneous decrease in SST farther north^{2,3}. SST variations in the tropical Atlantic, therefore, influence rainfall variations over Africa and Brazil. There are, however, other factors that influence the position of the ITCZ and the rainfall. Palmer³ finds that, in a general circulation model of the atmosphere, SST variations in the tropical Pacific Ocean have a significant effect on the position of the ITCZ over the Atlantic Ocean. This result suggests that the atmospheric convergence onto the region of unusually high SST in the eastern tropical Pacific in 1983 was the cause of the intense trade winds over the Atlantic in 1983. Palmer's calculations indicate that the high SST in the Atlantic during 1984 should have weakened the trade winds over the Pacific. Such a weakening was not observed—the trade winds over the Pacific were stronger than usual in 1984—possibly because SST in the tropical Pacific during 1984 were much lower than normal. There are factors, other than SST, that influence the atmospheric circulation in the tropics. For example, it has been suggested that an expansion of the Northern Hemisphere circumpolar vortex and an equatorward displacement of the subtropical high-pressure belt affect the tropical circulation and the rainfall of the Sahel⁴⁻⁷. The degree to which SST variations in the tropical Atlantic affect rainfall in the Sahel appears to be modest⁸ but there are indications that these SST variations have a more pronounced effect on rainfall over northeastern Brazil and southwestern Africa.

SST variations over large parts of the ocean are determined primarily by changes in the local flux of heat across the ocean surface. In the tropical oceans, however, SST variations are

strongly influenced by changes in the large-scale oceanic circulation, in response to changes in the surface winds. On seasonal and interannual timescales the strength of the wind determines the intensity of the oceanic circulation and the magnitude of the associated thermal gradients in the ocean. These gradients are reflected in SST patterns. For example, SST is uniformly high in March and April when the winds are relaxed and drive a weak circulation. The seasonal strengthening of the winds in May intensifies the oceanic circulation and increases the horizontal thermal gradients both in the surface and subsurface. The strong westward surface flow to the south of 3°N now transports warm surface waters from the Gulf of Guinea in the east to the western side of the ocean basin so that SST is much lower in the southeastern equatorial Atlantic than in the west. The unusually weak surface winds in 1984 maintained relatively small thermal gradients in the tropical Atlantic Ocean, primarily because isotherms in the Gulf of Guinea were exceptionally deep during the early months of 1984 (refs 9-11). An unusual eastward current between the Equator and 5 °S carried warm water into the Gulf of Guinea. Some of this water flowed southward along the African coast and suppressed coastal upwelling as far south as Angola and Namibia¹². Simulations of oceanic conditions in the tropical Atlantic during 1984 with a realistic general circulation model are in progress and should provide a coherent picture of how the circulation changed during the warm event.

From an oceanographic point of view, the unusual conditions in the tropical Atlantic Ocean during 1984 were caused by changes in the surface winds. From a meteorological point of view, the unusual winds were in part attributable to changes in the SST. This circular argument suggests that interactions between the ocean and atmosphere were of central importance. These interactions are crucial both seasonally and interannually.

(The large seasonal variations in SST near the Equator both influence the movements of the ITCZ and are influenced by the movements of the ITCZ which determine changes in the surface winds.) Interannual variations in the Atlantic Ocean can be viewed as perturbations to the seasonal cycle. In 1984, the seasonal migrations of the ITCZ took it further south than normal and it remained in a southerly position longer than normal. An unusual southward displacement of the ITCZ is also a feature of El Niño events in the Pacific Ocean. An additional feature of El Niño, but apparently not a feature of interannual variability in the Atlantic, is an eastward displacement of atmospheric convective zones at the western extreme of the ocean basin. Most studies 13-15 of interactions between the ocean and atmosphere in the tropics concern this zonal movement of convective zones. Studies of the air-sea interactions and the other factors that control the latitudinal movements of the ITCZ will shed light not only on phenomena such as droughts in western Africa and northeastern Brazil, but also on El Niño.

Finally, how often do warm events such as that of 1984 occur? The previous warm event with a comparable amplitude to the south of the Equator occurred in 1963 when the arid regions of southwestern Africa experienced severe floods, and a suppression of the coastal upwelling. However, the few available long time-series records show that there is considerable variability from year to year8. This variability is associated with the timing of the major feature of the seasonal cycle, the northward movement of the ITCZ. This movement starts abruptly so that the associated intensification of the south-east trades is sudden. In some (cold, dry) years, this happens as early as February, in some (warm, wet) years as late as June. Over the next decade, special oceanographic and meteorological measurements will be made in the tropical Atlantic to document this variability. This will be part of the international TOGA program, to study interannual variability of the tropical oceans and global atmosphere, over a 10-year period that started in 1985.

The anomalous meteorological and oceanic conditions in the tropical Atlantic basin during 1983-84 can be seen as an extreme example of a common historical pattern. Here we present time series of rainfall in subsaharan West Africa (SWA) and north-east Brazil (NEB), which show that departures in 1983-84 were severe, but not unprecedented. The associated sea surface temperature (SST) anomaly patterns included one that had previously been shown to accompany earlier years of extreme rainfall in SWA and NEB, and others that contained key elements of that pattern. The pattern concerned was recently shown to be a major mode of tropical Atlantic SST variation.

Figure 1 documents the interannual variation of rainfall in two contrasting parts of the tropical Atlantic basin, SWA (11-18° N) and NEB (3-8° S). Their rainy seasons, which occur at different times of the year (July-September core in SWA and March-April core in NEB), are associated with the two extremes of the annual cycle of the latitudinal position of the Intertropical Convergence Zone (ITCZ)¹. Each time series shown contains the yearly averages of normalized departures for a fixed set of stations (20 in SWA, 30 in NEB). The value for the year j is given by

$$\dot{X}_{j} = \frac{1}{N_{i}} \sum_{i=1}^{N_{j}} \frac{r_{ij} - \bar{r}_{i}}{\sigma_{i}}$$

where r_{ij} is that year's rainfall total at station i, \bar{r}_i and σ_i are respectively the mean and standard deviation of station i's yearly totals for the base period used (1941-82 for SWA, 1913-56 for NEB), and N_i is the number of stations with complete records in year j. The statistical advantages of this rainfall index formulation were originally summarized by Kraus², and its viability has

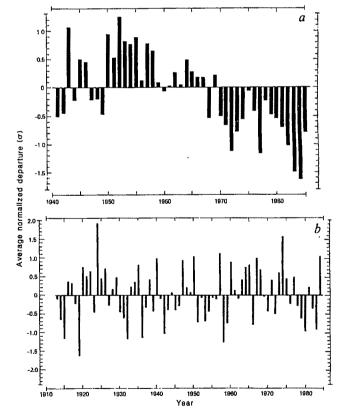

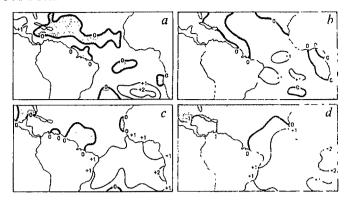

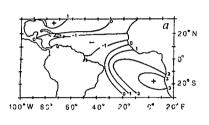

Fig. 1 Time series of yearly averages of normalized rainfall departures (in units of σ) for a, subsaharan West Africa (April-October) for 1941-85, and b, north-east Brazil (March-April) for 1913-84.

been confirmed by Katz and Glantz³. Further details on its use in this context appear in refs 4-6, where earlier versions of the time series were previously published for 1941-82 (SWA) and 1912-73 (NEB).

It is clear from Fig. 1 that 1983-84 was a period of anomalous rainfall in both SWA and NEB. Those two years were SWA's driest during 1941-84, and constituted the most recent extension

Fig. 2 Sea surface temperature (SST) anomaly maps (°C) for January 1983 (a), August 1983 (b), March 1984 (c) and August 1984 (d), from ref. 13. The March 1983 map would have been a better indicator of conditions during the NEB rainy season than that for January 1983, but was not available.

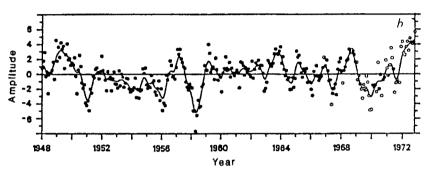

Fig. 3 Principal component 2 extracted from monthly normalized SST departures for 1948-72 (from ref. 12). a, Loadings multiplied by 10; b, amplitudes, with curve showing the result of applying a 13-point low-pass filter.

of a drought that has persisted, with very little respite, since 1968 (Fig. 1a). The widespread severity of the 1983-84 SWA drought conditions is fully documented in refs 7 and 8. Rainfall in that zone was also extremely deficient in 1972, 1977 and 1982, and moderately deficient during several other years since 1968, including 1985. Three moderately severe SWA drought years also occurred in the 1940s. The period spanning 1950-58, in contrast, was one of abundant rainfall in SWA, with strong positive departures in most of these years; weaker positive departures characterized 1959-67. SWA has thus experienced a pronounced decline of rainfall since the early 1950s.

In contrast to SWA, the anomalous 1983-84 rainfall in NEB consisted of both an extremely dry (1983) and an extremely wet (1984) year (Fig. 1b); each was among the 6-8 driest/wettest since 1913, and both ranked second in that regard for 1959-84. The stronger anomalies for this region are scattered throughout the record, which exhibits pronounced year-to-year variation. NEB rainfall shows little evidence of long-term trend, unlike that for SWA (Fig. 1). Hastenrath and Kaczmarczyk⁹ found that the variance of NEB rainfall includes a stronger high-frequency component (for example, periods of 2.5 and 5 yr) than does that of the Senegal river discharge, which reflects SWA rainfall. Much of the Senegal variance is centred on 30 yr, as is implied by the SWA time series in Fig. 1a, while NEB has a substantial portion of its interannual variance concentrated around 14 years. Preliminary reports (not shown) suggest that NEB rainfall was as abundant in 1985 as in 1984.

Figure 1 of ref. 10 documents the large-scale tropical Atlantic SST fields of June 1983 (a month lying between very deficient NEB and SWA rainy seasons; see Fig. 1 and discussion above) and June 1984 (lying between most abundant NEB and very deficient SWA rainy seasons). When converted to anomaly form, the 1984 pattern (see Fig. 2c, d) in particular is extremely similar to the one which has previously been shown to accompany earlier SWA drought and NEB flood years. That pattern, which was first identified by Lamb¹¹ (for SWA drought) and Hastenrath and Heller⁶ (for NEB flood), contains warmer than average surface water to the south of 10° N and east of 30° W, a feature that extends to at least 20° S, and colder than average surface

water to its immediate north and west. This pattern has been confirmed by the recent work of Lough¹², who showed it is a major mode of variation of tropical Atlantic SST (Fig. 3). The results of Lamb¹¹ and Lough¹² (including Fig. 3) collectively suggest that the above pattern has characterized many deficient SWA rainy seasons (for example, those in 1913, 1921, 1949, 1968, 1972 and, to a lesser extent, 1971), and did not occur during two periods (1927-34, 1950-56) when SWA was droughtfree (see Fig. 1). Furthermore, the magnitude of the pattern's correlation with SWA rainfall, as obtained using Lough's¹² principal component amplitudes shown in Fig. 2, is in the range 0.51-0.66 (26-44% of rainfall variance explained), depending on the timescale of the analysis. Hastenrath and Heller⁶ found that the same anomaly pattern characterized an SST composite for 10 extremely wet NEB years, and that the opposite pattern emerged from a treatment of 10 extremely dry NEB years.

Although the above SST anomaly pattern was not fully present during the very deficient 1983 SWA rainy season (Fig. 2b), the strong positive departures centred on the Equator probably displaced the zone of maximum SST southwards of its long-term average position. Lamb11 found the latter displacement to be an important consequence of the above SST anomaly pattern, and one that coincided with SWA drought. Note also that the positive SST departures in August 1983 were stronger between 5° N and 20° S than between 5 and 20° N. The SST anomaly field just before the deficient 1983 NEB rainy season (Fig. 2a) was also different in part from the NEB drought SST pattern described above. However, Fig. 2a does display the relatively large pool of abnormally cold water to the south of the Equator and the predominance of positive SST departures between 0 and 10° N. The 0-10° S SST anomaly pattern changed considerably from January to August of 1983 (Fig. 2a, b), in contrast to 1984 (Fig. 2c, d).

Equatorial Atlantic Ocean temperature and current variations during 1983 and 1984

Robert H. Weisberg* & Christian Colin†

* Department of Marine, Earth, and Atmospheric Sciences, North Carolina State University, Raleigh, North Carolina 27695-8208, USA † ORSTOM, 24 Rue Bayard, 75008 Paris, France

The equatorial regions of the Earth's oceans are climatically sensitive ones because of the zonal sea-surface temperature contrasts observed there1. Equatorial sea-surface temperature normally varies on an annual cycle with the prevailing trade winds but deviations from this cycle may have significant global implications as occurred for example during the 1982-83 Pacific Ocean El Niño/Southern Oscillation event². Understanding the annual and interannual variability of the tropical oceans has therefore been the goal of several measurement programmes. In the Atlantic Ocean, the Seasonal Response of the Equatorial Atlantic (SEQUAL) Experiment and the Programme Francais Ocean et Climat dans l'Atlantique Equatorial (FOCAL) have provided a basin-wide and synoptic data set over two annual cycles. We present here results from surface moored current meters which were one of several fixed and shipborne measurement systems employed by SEOUAL and FOCAL. We will describe the evolution of the upper ocean thermal and zonal velocity component variations in relation to forcing by the trade winds, show differences observed along the Equator at 28° W and 4° W, and compare the oceans responses at these locations during 1983 and 1984. The synoptic data realizations of these years differed from climatology and these differences are related to the rapidly varying nature and intensity of the wind stress in a given year. Changes in wind stress from year to year result in interannual variability as a modulated annual cycle and 1984, a year of weak winds relative to 1983, offers a case in point. The zonal sea-surface temperature gradient vanished along the Equator in 1984 during the season when it normally would have been a maximum.

The data were collected using vector averaging current meters suspended beneath taut moored surface buoys at depths of 10, 50, 75, 100, 150, and 200 m on the Equator at 28° W and at depths of 10, 35, 60, 85, and 110 m, on the Equator at 4° W. Sampling intervals for velocity and temperature were 15 min and these data have been low pass filtered to exclude fluctuations occurring at timescales shorter than 10 days to focus on the

Essentially, it is the zonal integral of easterly wind stress near the Equator that causes the annual cycle in the upper equatorial ocean velocity and temperature fields. Currents are generated which redistribute mass and together with equatorial long waves emanating from the boundaries these provide the mechanisms by which the ocean tends to adjust to the large-scale wind stress variations^{3,4}. Time series of surface wind velocity were collected during SEQUAL and FOCAL at St Peter and Paul Rocks (1° N, 29° W) and from buoys moored along the Equator at 24° W, 15° W and 4° W. The former are the most complete and they are representative of the temporal variations over the western twothirds of the equatorial Atlantic⁵⁻⁷. Katz et al.⁸ show the details of the wind stress variability during 1983-84 and the following large-scale features are noted for qualitative discussion. During 1983 the easterly component of surface wind stress intensified rapidly beginning in mid-April and remained strongly developed through mid-December. It then relaxed rapidly and remained weak through mid-May before intensifying rapidly again. Immediately before the seasonal intensifications during both years were short lived (around one week) relaxation events where the already weak easterlies got even weaker or reversed to become westerlies.

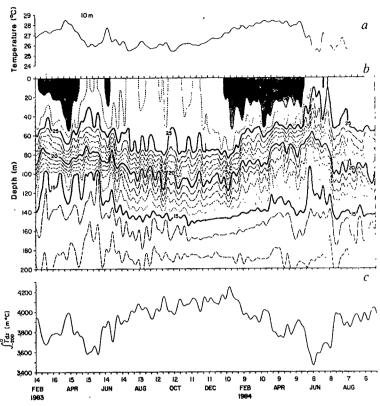

The effects of these variations in easterly wind stress on the upper ocean thermal and eastward velocity component fields are apparent in the SEQUAL and FOCAL data. Figure 1 shows the temperature variability over the upper 200 m on the Equator at 28° W along with the temperature at 10 m which is approximately equal to sea-surface temperature (SST) and the verticallyintegrated temperature which is proportional to heat content. Beginning in mid-April 1983, and coincident with the onset of increasing easterlies, a rapid shoaling of the isotherms and an attendant reduction in heat content is observed. This proceeds for around 1 month after which the isotherms deepen and the heat content increases to a relatively steady state lasting from August to December. Beginning in mid-December 1983 and coincident with the relaxation in easterly wind stress is a further deepening of the isotherms and an increase in heat content (peaking around mid-January) followed by shoaling through April. The thermocline has now completed one cycle in response to the winds and a repetition of this begins again during mid-May 1984 when the easterly wind stress intensifies again. The responses of the thermocline on the Equator at 28° W to the annual large-scale variations in easterly wind stress may, therefore, be summarized as sequences of shoaling and deepening (or conversely) leading to adjusted states. Accompanying these transitions are changes in the vertically-integrated temperature or heat content.

SST behaves differently to the thermocline depth. Note that while SST decreases to a minimum as the thermocline shoals beginning in mid-April 1983, it then remains low even after the thermocline has deepened to its adjusted state. In so doing, minimum SST on the Equator at 28°W coincides with a deepened thermocline and increased local heat content. The opposite occurs following the mid-December easterly wind stress relaxation resulting in maximum SST on the Equator at 28°W after the thermocline has shoaled and the local heat content has decreased.

Corresponding plots for the eastward velocity component, its vertical integral, and surface value are shown in Fig. 2. The flow is primarily eastward over the entire 200 m domain with only intermittent westward flow at the surface associated with the south equatorial current (SEC). The core of the equatorial undercurrent (EUC) is observed between 50 and 100 m and its position moves downward with the thermocline as the latter adjusts to increased easterly wind stress around June and July of both 1983 and 1984. While the vertical position of the EUC core migrates annually with the thermocline a clear annual variation in EUC speed or transport is not readily apparent.

Similar plots for the temperature and eastward velocity component observed on the Equator at 4°W are shown in Figs 3 and 4 respectively. The thermocline at 4°W also undergoes a sequence of shoaling followed by deepening beginning in Mid-April 1983 and again in mid-May 1984, and a sequence of deepening followed by shoaling beginning in mid-December 1983. Several important differences between the responses at both longitudes are evident, however. First, the shoaling/deepening and deepening/shoaling sequences at 4° W are of longer duration and larger magnitude than those at 28° W.

Fig. 1 Thermal structure observed over the upper 200 m on the Equator at 28° W from February 1983 to October 1984. a, The temperature at 10-m depth; b, isotherm depths as a function of time; c, vertically integrated temperature proportional to heat content. The data have all been low pass filtered to remove fluctuations with timescales <10 days. Temperatures >27°C are stippled to highlight the warmest surface temperatures relative to the thermocline depth.

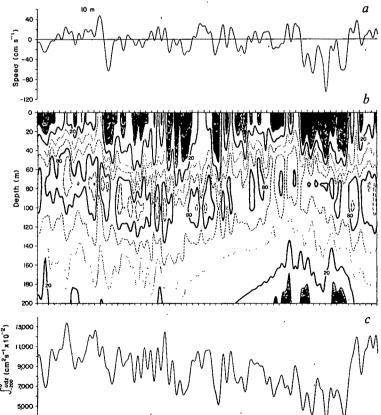

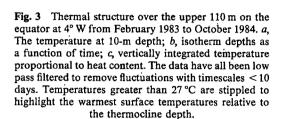

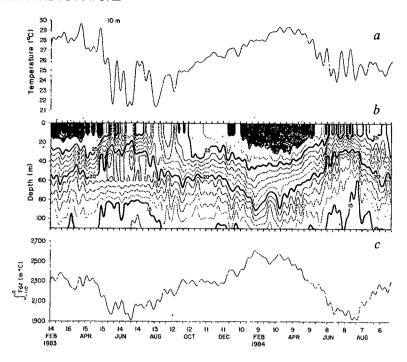

Fig. 2 Eastward component of velocity (u) observed over the upper 200 m on the Equator at 28° W from February 1983 to October 1984. a, u at 10 m depth; b, u isotach depths as a function of time; c, the vertical integral of u. The data have all been low-pass filtered to remove fluctuations with timescales <10 days. Regions of westward flow are stippled.

This is true for both the vertical position of a given isotherm within the thermocline as well as for SST. Not only does the Gulf of Guinea have the coldest SST along the Equator in the Atlantic Ocean during summer, it also has the warmest SST during winter. Owing to the increased duration of the response sequences the annual variations show a more sinusoidal appear-

ance at 4° W than at 28° W (where the thermocline attained an adjusted equilibrium to increased easterly wind stress for several months in 1983). Because it takes longer for the thermocline at 4° W to adjust to increased easterlies than at 28° W, SST is more nearly in phase with the thermocline at 4° W although SST still remains low even after the thermocline begins to deepen there.

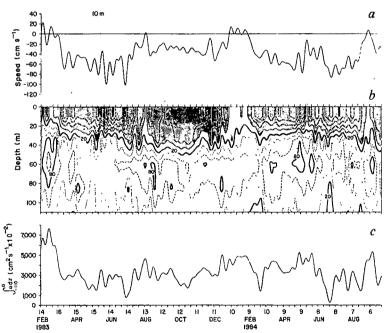

Fig. 4 Eastward component of velocity observed over the upper 110 m on the Equator at 4° W from February 1983 to October 1984. a, u at 10-m depth; b, u isotach depths as a function of time; c, the vertical integral of u. The data have all been low-pass filtered to remove fluctuations with timescales <10 days. Regions of westward flow are stippled.

Second, we observe an additional shoaling period at 4°W between October and December 1983 which is not evident at 28°W. Third, the deepening response at 4°W beginning in mid-December 1983 is much more pronounced than that at 28°W resulting in a well-defined peak in vertically integrated temperature at 4°W during February and March 1984. The corresponding change in dynamic height between the surface and 110 m due to the increased temperature is ~8 dynamic cm in agreement with the FOCAL hydrographic section data obtained at that time⁸.

In the zonal velocity component, the principal difference between 4° W and 28° W is a much more persistent and stronger westward SEC on the surface at 4° W. Below the surface and down to the observational limit of 110 m the flow is eastward and the position of the EUC core deepens with the thermocline as at 28° W.

Before SEQUAL and FOCAL our view of the annual cycle was based on climatologically-averaged monthly fields derived

from decades of ship reports⁹⁻¹¹. Linear and non-linear numerical models¹²⁻¹⁴, driven by climatological wind fields, have been successful in emulating the vertically integrated climatological thermal field. The new basin-wide synoptic data show significant differences between the annual cycle of a given year and the climatological mean annual cycle. Rather than a slowly varying response nearly in phase with the easterly wind stress component the thermocline undergoes sequences of deepening and shoaling varying in both duration and magnitude along the Equator. These differences are related¹⁵ to the rapidly varying nature of the wind stress observed in any given year versus the slowly varying nature of the climatology; a property inherent in averaging data from many years with varying phase. Historical shipboard observed wind data when displayed by individual years 16 rather than averaged show that rapid transitions are, indeed, the normal occurrence. Variations in the wind stress development from year to year will, therefore, give rise to interannual variability as a modulated annual cycle and this is evident in comparing the 1984 and 1983 responses; years of relatively weak and strong surface easterlies respectively^{8,17}. At 28° W, the shoaling portion of the annual cycle shows the 20°C isotherm some 20 m higher in May and June 1984 than in 1983. At 4° W. the deepening portion of the cycle shows the 20 °C isotherm some 30 m deeper in February and March 1984 than in 1983. The zonal distribution of upper ocean heat content was therefore different during these years with more heat in the eastern side of the basin during 1984.

SST along the Equator was also quite different. In 1984, from June to August, SST was roughly 1 °C colder at 28° W (25 °C versus 26 °C) and 3 °C warmer at 4° W (24.5 °C versus 21.5 °C) than over the same period in 1983. Consequently, during the cold season of 1984, the zonal SST gradient along the Equator had essentially vanished when it normally should have been a maximum. During the warm season (February and March) SST was warmer by roughly 1 °C at both 28 °W and 4° W in 1984 than in 1983. These SST differences seem to be linked with the differences reported in the position of the Intertropical Convergence Zone¹⁷ during these years.

While vertically integrated temperature and SST both differed from 1983 to 1984 it is reiterated that these two quantities are not related in a simple manner. At 28° W minimum SST coincides with a deepened thermocline. At 4°W minimum SST occurs while the thermocline is deepening. In either case, vertically integrated upper ocean temperature or heat content alone is not adequate to account for air-sea heat exchange since this process depends on SST.

Variations in the velocity field appear to be more complicated than those in the temperature field and the relative importance of horizontal and vertical advection in the heat balance has not yet been assessed. Note that at 28° W during March-June 1983 the transport per unit width on the Equator was nearly double the amount observed during those months in 1984.

We have presented a subset of the SEQUAL and FOCAL moored current meter data showing the evolution of the annual cycle in upper ocean zonal currents and temperature along the Equator. Differences found between climatological data inference and synoptic data realization are related to the rapidly varying nature of the easterly surface wind stress component observed in any given year versus the slowly varying climatology. In 1984, a year of relatively weak winds compared with 1983, the eastern portion of the basin showed increased values of vertically integrated temperature and SST during the winter/spring and summer seasons respectively. These changes in the zonal distribution of temperature along the Equator in the Atlantic Ocean have similarities with the El Niño occurrences in the Pacific Ocean.

During 1983 and 1984 oceanographers from France and the USA conducted an extensive field programme in the tropical Atlantic Ocean. The principal goal was to document the annual cycle, but unexpectedly a difference was observed between the two years. We describe here the observed variations in the thermal field and in the zonal currents along several meridians. In early 1984, the upper ocean especially on the eastern side of the ocean basin was substantially warmer than during the corresponding period a year earlier. Most of this change in the heat content was the result of a deeper thermocline. During this time an unusual eastward surface current appeared to the south of the Equator undoubtedly contributing to large zonal heat fluxes. The decrease in the surface winds¹ between 1983 and 1984 is presumably responsible for these changes. Inspection of the few available long records reveals that in the Atlantic warm events such as that of 1984 are rare and that the previous event with comparable amplitude occurred in 1963.

Oceanic conditions in the tropical Atlantic have a pronounced annual cycle which is almost in phase with the annual changes in the surface winds. When the winds near the Equator are relaxed, in March and April, horizontal thermal gradients are at a minimum and the surface currents are weak and westward. These currents feed the Brazilian coastal current which flows northwestward into the Gulf of Mexico. The intensification of the south-east trade winds from May onwards results in a dramatic change in the oceanic circulation. The westward surface flow, to the south of 3° N approximately, accelerates while an intense eastward surface current appears between 3° N and 9° N approximately². The Brazilian coastal current now veers offshore near 5° N to maintain the eastward flow3. The associated changes in the thermal field include a deepening of the isotherms in the western equatorial Atlantic, especially in the neighbourhood of 3° N, and an elevation of isotherms of the Gulf of Guinea and near 9° N in the western side of the ocean basin⁴. These changes in the thermal structure affect the sea-surface temperatures which decrease at, and to the south of, the Equator in the central and eastern Atlantic once the south-east trade winds start to strengthen.

The field work conducted in 1983 and 1984 was part of the Seasonal Response of the Equatorial Atlantic (SEQUAL) and Français Ocean et Climat dans l'Atlantique (FOCAL)

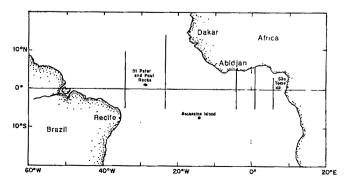

Fig. 1. Equatorial Atlantic Ocean with the meridional sections used in this study.

programmes, and it provided extensive observations of the thermal structure in the equatorial Atlantic during that period. Preliminary results from the first year (1983) measurements are given elsewhere⁵. Data for this study were derived from several sources. These include meridional hydrographic sections along 34° W, 23° W, 4° W, 1° E and 6° E (Fig. 1) that were made four times each year by the research vessels *Capricorne* and *Nizery*. On these sections, temperature and salinity were measured by means of a CTD (conductivity temperature/depth), currents were measured by means of a profiler⁶ at the station locations shown in Fig. 2. Additional data were derived from aircraft and ship-of-opportunity expendable bathythermographs.

We shall confine our discussion to the temperature structure along 23° W, 4° W and 6° E measured in January-February and in July-August of 1983 and 1984. The depth of the 20 °C isotherm along these sections is shown in Fig. 2. The 20 °C isotherm lies within the thermocline and is thus representative of the thermal structure in the upper 100 m of the water column. The most striking difference between the sections made in the two years is the increase in the average temperature of the upper ocean. between February 1983 and February 1984. This warming was most pronounced in the Gulf of Guinea where the thermocline in some places was 30 m deeper than normal in February 1984 throughout the entire section. The equatorial temperature profiles shown in Fig. 3 illustrate this change. In 1983, the thermocline depth was approximately equal to the climatological mean value, whereas in 1984 it was approximately three standard deviations below the mean. This condition was so anomalous that in January and February 1984 the thermocline which usually slopes downward to the west was practically horizontal⁸. Time series measurement along the Equator indicate that the unusual warming started as early as November 1983 and persisted into May 1984. The warm water that accumulated in the Gulf of Guinea was unusually saline which indicates that its origin was the western side of the ocean basin.

Sections along 23°W show that the meridional gradient of shallow isotherms (not shown in Fig. 2) increased significantly to the south of the Equator between February 1983 and February 1984. This implies an eastward geostrophic current between the Equator and 5°S in February 1984. Normally the surface flow in this region is westward. Direct measurements with current profilers averaged over 0-20 m depth confirm this unusual eastward current which penetrated into the Gulf of Guinea (Fig. 4). The current is absent from sections made in April 1984 but appears again in July 1984. Presumably this current played an important role in transporting warm saline surface waters into the Gulf of Guinea thus increasing the average temperature of the upper ocean in that region. There is evidence that the eastward north equatorial countercurrent, to the north of 3° N. also contributed to the unusual accumulation of warm surface waters in the eastern equatorial Atlantic. Some of this warm water flowed southward along the African coast and may be a factor in inhibited coastal upwelling as far south as Angola and Namibia¹⁰.

The change in the surface winds^{1,8} between 1983 and 1984 was presumably responsible for the change in the oceanic circulation between those two years. The westward winds maintain the zonal density gradients in the ocean so that the unusually weak winds in early 1984 resulted in the reduction of the zonal slope of the thermocline during January and February and the associated eastward transfer of warm surface waters. That this transfer occurred primarily in the eastward current to the south of the Equator, and in the eastward north equatorial countercurrent to the north of 3° N approximately, suggests that there were significant changes in the curl of the wind during 1984. The curl is large in the neighbourhood of the Intertropical Convergence Zone (ITCZ) which is usually over the north equatorial countercurrent to the north of 3° N. It is intriguing that from satellite cloud images in early 1984 a second ITCZ was observed to the south of the Equator where the unusual eastward current

appeared (J. Citeau and B. Guillot, personal communication). The relations between this current, the ITCZ, and the curl of the wind are now being studied. Another topic under investigation is the relation between the north-westward flowing Brazilian coastal current and the eastward currents. This coastal current, as mentioned earlier, absorbs water from the westward currents and, in turn, maintains the eastward flow to the north fo 3° N approximately. It is not yet known whether the unusual eastward current to the south of the Equator in early 1984 was fed by the Brazilian coastal current.

There are many similarities between oceanographic conditions in the tropical Atlantic in 1984 and 1963 when a comparable warm event occurred. Not only were sea-surface temperatures exceptionally high in 1963, but there were also reports of unusual eastward surface currents to the south of the Equator, and of the intrusion of warm saline water into the coastal regions of Angola and Namibia where local coastal upwelling was inhibited¹¹⁻¹⁴. Occurrences such as these are very similar to but much less frequent than El Niño events in the Pacific Ocean. In the Atlantic, interannual variability on shorter timescales has a relatively small amplitude but is, nonetheless, of considerable interest because the physical processes involved in the major events are likely to be the same as those involved with smaller amplitudes.

Annual change of sea surface slope along the Equator of the Atlantic Ocean in 1983 and 1984

For two years beginning in October 1982, oceanographic observations were made in the equatorial Atlantic to investigate the relationship between sea level, wind stress, sea surface slope (zonal pressure gradient, thermocline depth) and equatorial currents. Here we describe the sea surface slope derived from three complementary methods: hydrographic stations, pressure gauges and inverted echo sounders. The latter two have the advantage of yielding continuous time series, but depend on the hydrographic stations for an absolute reference. Together, the three provide a detailed description of the temporal variation of the sea surface slope which is then compared to a wind-stress time series. The dominant signal, in both sea slope and wind stress, is the annual cycle, although amplitude and phase vary interannually. The annual increase in sea surface slope along the Equator in the western and central basins lags the onset of the south-east trade wind. During the boreal winter of 1983-84 a strong rise in sea level occurred against the African coast, accompanied by a levelling of the sea surface to the west. At the same time, an almost complete relaxation of eastward wind stress on the Equator was observed near the centre of the basin.

The sea surface along much of the Equator in the Atlantic and Pacific oceans slopes upward to the west. This slope reflects a shallowing of the thermocline toward the east and results in a zonal pressure gradient in the uppermost 100 m which is essential to the existence of the Equatorial Undercurrent¹. The

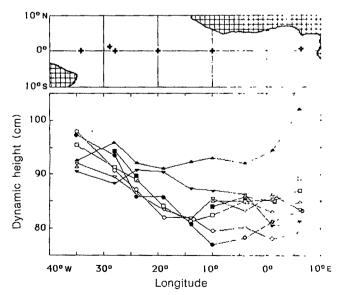

Fig. 1 Quarter-annual dynamic height of the sea surface, relative to 500 m. □ (■), October-November 1982 (1983); △ (▲), January-February 1983 (1984); ∇ (**V**), April-May 1983 (1984);) (**•**), July-August 1983 (1984). Individual points are either mendional averages of casts within 0.5° of the Equator or zonal averages of casts within a 5° band along the Equator. Locations of inverted echo sounders, a wind recorder and pressure gauges discussed in the text are indicated in the chart above. The shaded areas are the bounding continents.

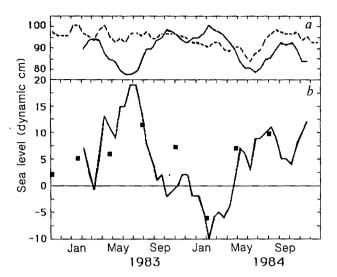

Fig. 2 Sea level difference (b) between St Peter and St Paul Rocks (29° W) and São Tomé island (7° E) . The individual traces are shown in a (dashed line, 29° W ; solid line, 7° E). The dynamic level at each site is determined by comparison with hydrocast dynamic height, 0 relative to 500 m. The differences in dynamic height from nearby hydrographic stations (near the Equator at 28° W and 6° E) are shown as points, although the casts were not simultaneous.

latter is a major zonal current in the tropics which, in 1979, transported an annual average of 20×10^6 m³ s⁻¹ of near-surface water from west to east in the Atlantic^{2,3}. A change in the mean level of the sea surface is a direct indication of a change in heat storage in the upper few hundred metres of that region, and a zonally differential change in mean level varies the acceleration force imposed on the fluid by the zonal pressure gradient.

The pressure gradient has a seasonal signal: weak in the boreal spring followed by a stronger gradient in the summer and autumn⁴⁻⁶. Six quasi-synoptic observations, obtained during three different years, found gradients at the surface ranging from 0.7 to 7.3×10^{-5} dyn g⁻¹ (ref. 4). (The values are reported as accelerations obtained by dividing the pressure gradient by a density of $\sim 1 \, \mathrm{g \ cm^{-3}}$). Furthermore, the seasonal cycle is roughly in phase with the zonal wind field, both as reported by the ships during the discrete hydrographic observations and as compiled from the historical record⁴. Incomplete observations during 1979 of wind, sea surface height in the west and transport of the equatorial currents were compared to a simplified windforced model with encouraging results⁷.

Hydrographic data were obtained during eight cruises of both the Capricorne and Nizery between October 1982 and August 1984. Figure 1 shows the result of this work as the dynamic height at the surface, relative to 500 m. Gradients derived from the data west of the Gulf of Guinea are shown in a later figure. The slope of the sea surface in the Gulf is generally weak and without a preferred direction, except in January-February 1984, when there was a rapid rise in height approaching the African coast.

Pressure gauge data (Fig. 2) were obtained at 7° E and 29° W. The sensors were placed at depths of <10 m (in order to be equivalent to tide gauges), adjacent to the only two equatorial islands in the Atlantic; namely, São Tomé (0°15' N, 6°40' E) and St Peter and St Paul Rocks (0°55' N, 29°21' W). Half-monthly averages were compared with the average of several hydrocasts, each made seven times at each site during the record in order to get a consistent dynamic level between the two sites. The standard deviation of the difference between hydrographic and pressure gauge data, after adjustment for the mean, was ± 3 cm. The difference between the two gauges is plotted in Fig. 2b.

As shown in Fig. 1, the difference in dynamic height between 7° E and 29° W combines both the westward upward slope and the Gulf of Guinea slope. Thus the negative (westward downward) slope shown in Fig. 2 from December 1983 to mid-April 1984 is not a basin-wide reversal in surface tilt, but probably a neutral slope over much of the basin and a large height increase against the African coast. It confirms the suggestion from the hydrographic data that this condition did not occur in the previous 12-month period. The second clear contrast between the two years is the size of the positive difference in the summer, which was only half as large in 1984. This is not seen in the hydrographic data because of the discrete sampling.

Of the six inverted echo sounders deployed along the Equator during 1983-84, results from the four at 34° W, 28° W, 20° W and 10° W are discussed here. (A record at 1° W showed no substantial difference from that at 10° W and a short record at 38.5° W is omitted.) An inverted echo sounder is similar to a tide gauge in that it provides a measure of the vertically integrated temperature of the entire water column. To convert this to dynamic height, the hydrocasts are used to determine mean values, and historical data⁷ are used to relate a change in the observed travel time to a change in dynamic height. The standard deviation of the difference between the sounder-derived dynamic height and the hydrographic data is ±2 dynamic cm.

The four resulting time series were low-pass filtered to remove tides and inertia-gravity waves. A linear regression analysis was then performed zonally on the data once every 10 days: the result is shown in Fig. 3, along with an indication of the goodness of fit. Also shown is the pressure gradient estimated from the hydrocast data (Fig. 1) for the same region. The 17-month time series derived from the four sounders shows the development of the zonal pressure gradient in the boreal spring of 1983, its gradual relaxation over a 9-month period and its subsequent redevelopment in 1984. This redevelopment occurred very rapidly during the first 20 days of June; the 1984 maximum exceeded that of 1983 by ~20%.

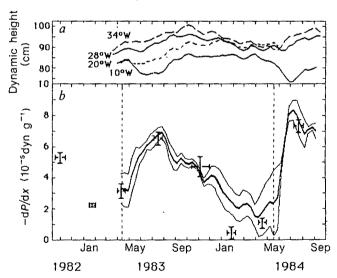

Fig. 3 Dynamic height (a) and zonal pressure gradient (b) between 34° W and 10° W along the equator. The solid line in b is the gradient computed at 10-day intervals from four inverted echo sounder records (shown in a). The bounding curves are determined from the standard error of the slope of the linear regression and, while not a true measure of statistical significance, they are a measure of linearity. The points (with error bars) are from the hydrocast data (Fig. 1) for the same region. The horizontal bar shows the time interval during which the casts were made; the vertical bar indicates the standard error of the slope (from a linear regression of (typically) six averages as plotted in Fig. 1). The dashed lines indicate the time of onset, each year, of the south-east trade wind (see Fig. 4).

In general, the hydrocast data (points in Fig. 3) yielded the same gradients, but with one important discrepancy. In the latter half of January 1984, the hydrographic data show no significant gradient. From Fig. 1 we note that this section (solid triangles. apex up) recorded an unusual sea surface slope, and a higher surface at every site (except for the westernmost location) than at any other time in the two years. Also, the 1984 surface is typically 10 cm higher than at the comparable time in 1983, increasing to nearly 20 cm near the eastern boundary. This anomaly is indirectly confirmed by the pressure gauge data (Fig. 2), which further suggests that this situation, although most pronounced near the time of the survey, was sustained during the months of January-March.

In contrast, the sounders did not indicate a minimum in pressure gradient during these months. Neither the sounder at 10° W, nor the one at 1° W not included in Fig. 3, indicated a high surface height. Indeed, the comparison between sounders and hydrocasts at these two sites showed discrepancies of 6 and 8 cm, several standard deviations more than the general result from the comparison. We cannot yet explain the different results from the two observational methods.

The objective of obtaining a time series of the zonal pressure gradient is to compare it with the synoptic wind field. The annual cycle of the trade winds along the Equator and west of the Gulf of Guinea results from the meridional migration of the Intertropical Convergence Zone (ITCZ), which is located near the Equator at the beginning of the year and reaches to beyond 10° N six months later. Horel et al.8 remark on a rapid relaxaton of the near-surface wind field between November 1983 and January 1984, during which time the ITCZ shifted southward and then remained south of the Equator until May. Unlike the oceanographic data, which have only a meager and patchy historical base, the meteorological data are sufficiently complete for Horel et al.8 to conclude that conditions over the Atlantic in 1983-84 constituted an extreme event.

Our interest here is in the surface wind field directly over the Equator, in the band from the Gulf of Guinea to the South American coast. To characterize that wind field a wind recorder was placed on St Peter and St Paul Rocks: Fig. 4 shows the zonal wind stress computed from this record. From the historical data we know that this location is typical of the central and western reaches of the equatorial Atlantic, with stress increasing from east to west⁹. The record in Fig. 4 shows sudden increases in westward wind stress in the boreal spring of each year. A similar picture was obtained at the same site in 1979¹⁰ and in 1985 (S.L.G. and E.J.K., unpublished data), but the date of onset varies each year over a range of \sim 2 months.

The low wind stress observed from mid-January to May 1984 reflects the southerly location of the ITCZ in early 1984. The negative (eastward) stress in May is unusual. In an objective analysis of ship-reported winds (1964-84), Jacques Servain (personal communication) computed a monthly average eastward wind stress in the area of St Peter and St Paul Rocks only for May and June 1968. In 1983 and 1984, the onset of high wind stress leading to the seasonal trade wind occurred on 5 April and 19 May, respectively. These dates are indicated by dashed lines in Fig. 3, and they show the near simultaneity of the westward wind onset and the build-up of the zonal pressure gradient. A lag-correlation calculation between the data of Figs 3 and 4 indicates that the ocean surface height lagged the wind (at this one site) by 10-15 days. We note that the lower wind stress in mid-1984, relative to 1983, is associated with a larger maximum zonal pressure gradient in 1984.

The quarter-annual hydrographic surveys provide the densest set of classical observations yet obtained in the equatorial Atlantic, and the inverted echo sounder array is unique. The data confirm our previous understanding that the basin comprises two different regions of response, roughly delineated by the Gulf of Guinea. To the west of the gulf the hydrographic sampling proved adequate to define the annual variation of the

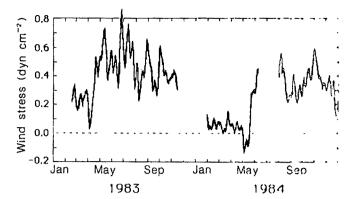

Fig. 4 Low-pass-filtered westward wind stress at St Peter and St Paul Rocks (29° W), 1983-84. The filter admits >95° of the variance for frequencies less than 0.1 cycle per day

zonal pressure gradient, relative to the results from the continuously sampling sounders. The range of values, 0-8 x 10⁻⁵ dyn g⁻¹, is comparable to earlier estimates. The previous low value, obtained in the spring of 1963, was also associated with a particularly strong relaxation of the trade winds⁴. Both methods of observation show a slow and nearly monotonic decrease in zonal pressure gradient from August 1983 until May 1984, followed by a sharper and larger increase in gradient in the spring of 1984, relative to 1983. The hydrocast data show an anomalously high surface (deep thermocline) in January-February 1984 not evident in the sounder data: this difference needs further investigation.

The pressure gauge data (Fig. 2) compare the western central region with the eastern boundary of the Gulf of Guinea and also show an annual signal superimposed on an interannual difference in level. Around July of each year, a peak is seen in the sea surface height difference between west and east, and a minimum is found to occur around February. In 1984 the minimum is strongly negative (that is, the thermocline is deeper in the east), in agreement with the hydrocast data.

The zonal wind stress from 29° W (Fig. 4) has a boxcar-like time dependence: low in the boreal spring when the ITCZ is at or near the Equator and high when the south-east trade winds prevail. There is however an interannual difference, with the amplitude of the zonal stress in 1984 consistently lower than that in 1983 by ~0.15 dyn cm⁻² throughout the entire year. The lower stress during 1984, however, resulted in a larger zonal pressure gradient west of the Gulf of Guinea which, unless opposed by other differences, would be expected to alter the equatorial circulation. The timing of the onset of the south-east trade winds is closely correlated with the build-up of the zonal pressure gradient. Our data imply a response time for the ocean of 10-15 days.

Atmospheric conditions in the Atlantic sector during 1983 and 1984

John D. Horel*, Vernon E. Kousky† & Mary T. Kagano‡

The dramatic global climate variability during the period from 1982 to 1984 has presented a unique opportunity to diagnose and interpret the role of air/sea interactions over the tropical oceans. Recent reviews have summarized the observational and numerical evidence for air/sea interactions over the equatorial Pacific Ocean associated with the El Niño/Southern Oscillation (ENSO) phenomenon¹⁻³. Here we present details of the atmospheric conditions in the Atlantic sector between 1983 and 1984. During the latter half of 1983, the atmospheric circulation over the equatorial Atlantic underwent a dramatic reversal: surface trade winds were substantially reduced; surface pressures decreased; and cloudiness and rainfall increased over the ocean and adjacent regions of north-east Brazil. These regional changes over the equatorial Atlantic coincided with planetary-scale adjustments in the tropical atmosphere. While the atmospheric circulation over the tropical Pacific was experiencing an extraordinary departure from normal during 1983, as evidenced by a reversal in direction of the surface winds, the circulation over the Atlantic was in a building-up phase with stronger than usual surface winds. As the atmospheric circulation over the Pacific returned to normal during the latter half of 1983, the trade winds over the Atlantic relaxed.

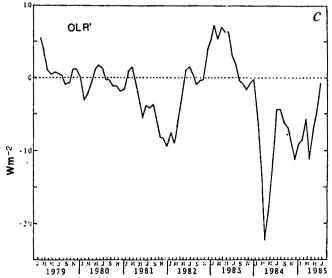

To place the atmospheric conditions over the Atlantic sector during 1983-84 in context, it is helpful to review the salient features of the global tropical circulation during this period. More detailed accounts of the month-to-month variability of the global circulation are given in the seasonal reviews⁴⁻¹⁰ and monthly Climate Diagnostics Bulletins. Over the equatorial Pacific, the largest climatic anomaly of the atmosphere-ocean system during the past 100 years was observed during the latter half of 1982 and early part of 1983 (refs 1-3). The conditions during this period represented an extreme 'warm' phase of the ENSO phenomenon, where 'warm' refers to the unprecedented increase in sea surface temperature in the equatorial Pacific. Some of the significant atmospheric circulation features observed during this period are: weakening of the Pacific trade winds and strengthening of the Atlantic trade winds: reduction of surface pressures over the eastern equatorial Pacific and increased pressures over Indonesia and the equatorial Atlantic; torrential rainfall over the central and eastern equatorial Pacific and drought over Indonesia and north-east Brazil.

While the 1982-83 ENSO warm phase in the equatorial Pacific has been well documented, its collapse during mid-1983 and

Fig. 1 Indices of: a, monthly averaged sea surface temperature (top) and departures (bottom) of the monthly averages from the climatological means 18; b, 200-mbar zonal wind anomalies (top) and 850-mbar zonal wind anomalies (bottom); c, monthly anomalies of outgoing long-wave radiation. The indices are based on observations within the region 5° N to 5° S and from 35° W to 10° W. The anomalies of 850- and 200-mbar wind (outgoing long wave radiation) are computed with respect to the 1978-83 (1974-83) base period. To smooth month-to-month irregularities in the data, a 3-month running mean filter has been applied to the indices. The 1980-85 mean anomaly has been removed from the sea surface temperature anomaly index, to compensate for trends in the long-term sea surface temperature record.

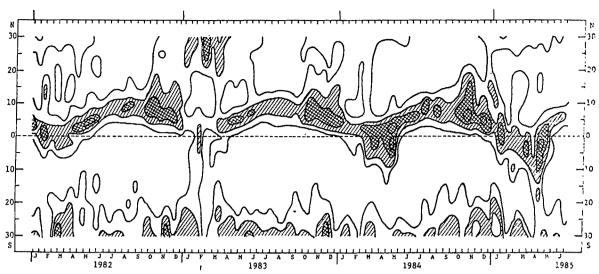

Fig. 2 Time versus latitude plot of outgoing long-wave radiation (OLR) averaged over the latitude band 20-35° W. OLR values > 240 W m⁻² are indicated by a lack of hatching; hatching denotes OLR values between 220 and 240 W m⁻²; cross-hatching indicates values less than 220 W m⁻²; the contour interval is 20 W m⁻².

subsequent reversal into a 'cold' ENSO phase have received less attention. In many respects, the tropical circulation during 1984 was as unusual as that during the preceding year: decreased ocean temperatures in the central equatorial Pacific and increased temperatures in the equatorial Atlantic; strengthening of the Pacific trade winds and weakening of the Atlantic trade winds; higher pressures over the eastern equatorial Pacific and decreased pressures over Indonesia and the equatorial Atlantic; dry conditions over the central equatorial Pacific and above normal rainfall over Indonesia and north-east Brazil.

Briefly, the anomalous atmospheric conditions during 1983 (1984) over the equatorial Pacific can be explained largely in terms of the atmospheric response to the unusually warm (cold) ocean surface^{1-3,11-13}. Similar processes undoubtedly had a role over the equatorial Atlantic during 1984. Because of the sensitivity of the tropical atmosphere to relatively small changes in equatorial sea surface temperature, sea surface temperature is often regarded more as an atmospheric variable than an oceanic one. In the following, we will contrast the changes in sea surface temperature in the equatorial Atlantic to those in the overlying atmosphere during 1983–84. In addition, we will compare the relative magnitudes and durations of the anomalous conditions in the Atlantic sector during this period to those over the Pacific associated with ENSO.

Figure 1 contrasts a number of indices of the sea surface temperature and selected atmospheric fields. The month-to-month changes in sea surface temperature averaged over the central equatorial Atlantic from 5° N to 5° S and 35° W to 10° W are shown in Fig. 1a for the period 1980–85. During every year, sea surface temperature exhibits a pronounced annual cycle with the highest (lowest) temperatures during February-April (August-October)^{14,15}. Note that the warmest ocean surface (>28.5°C) was evident during February-May 1984. In contrast, averages of sea surface temperature for the central equatorial Pacific exhibit less of an annual cycle and more variability from year to year^{16,17}.

The departures from climatology¹⁸ of central equatorial Atlantic sea surface temperature are also shown in Fig. 1a. Large positive anomalies were observed in late 1981; however, these occurred primarily during the cool phase of the annual cycle. Sea surface temperature was near or slightly below normal from mid-1982 until late 1983. After the beginning of 1984, the sea surface became anomalously warm in the equatorial Atlantic, with peak anomalies occurring during August-September. The anomalies decreased thereafter but remained positive until June 1985. The magnitude (<1 °C) of the sea surface temperature

increase in the equatorial Atlantic during 1984 is modest compared with that in the Pacific during 1983 (2-3 °C).

To first order, the fluctuations in the atmospheric circulation over the equatorial Atlantic can be viewed as perturbations of the mean zonally oriented circulation cell characterized by rising motion over the Amazon Basin, surface inflow from the Atlantic trade winds (directed from east to west), and outflow aloft (directed from west to east). Superimposed on this mean zonal circulation are large seasonal meridional migrations of the Intertropical Convergence Zone (ITCZ), an east-west oriented band of extensive cloudiness and rainfall. Indices of 850-mbar zonal wind (indicative of the surface trade-wind field) and 200-mbar zonal wind (representative of the flow in the upper troposphere) for the region used for the sea surface temperature index are shown in Fig. 1b. Positive (negative) values of the 850-mbar wind index indicate weaker (stronger) than normal surface trade winds over the equatorial Atlantic. The most striking features of the near-surface wind field are the gradual buildup of the trade winds during mid-1982 and their rapid relaxation between November 1983 and January 1984. The effects of these changes in surface wind stress on the ocean circulation are discussed in refs 19-24.

The out-of-phase relationship between near-surface and upper tropospheric winds is evident in Fig. 1b. In contrast to the near-surface winds, year-to-year fluctuations in the upper tropospheric winds are strongly modulated by the annual cycle such that the largest anomalies are observed from January to April of 1983 and 1984.

Figure 1c shows the month-to-month changes in outgoing long-wave radiation averaged over the region used for the other indices. Outgoing long-wave radiation provides an indication of cloudiness and deep tropical cumulus convection: positive (negative) anomalies of outgoing long-wave radiation indicate warmer (colder) cloud-top temperatures and less (more) cloudiness and rainfall than usual. Rainfall and cloudiness were inhibited during February-May 1983 while they increased substantially during February-May 1984.

As mentioned above, variations in cloudiness and rainfall over the equatorial Atlantic are strongly modulated by the seasonal meridional migrations of the ITCZ. The ITCZ normally extends furthest south and straddles the Equator in the western and central Atlantic from February to April. Figure 2 shows the meridional migrations of the ITCZ during the period from 1982 to 1985 in terms of a time-latitude plot of outgoing long-wave radiation averaged over the longitude band 20° W to 35° W. Note that the ITCZ was noticeably weak and slightly further north

during February-April 1983, compared with the other years. During March-May of 1984 and 1985, the ITCZ was vigorous and expanded southward.

The variations in cloudiness and rainfall evident in Figs 1c and 2 for the equatorial Atlantic extend westward into the region of north-east Brazil. Figure 3 contrasts the distribution of anomalous rainfall during 1983 and 1984 during the normally rainy seasons of March-May. The anomalies of rainfall at each station have been normalized by the climatological mean rainfall for that season so that the figures are not biased towards the Amazon regions, which receive more rainfall than the drought-prone areas of north-east Brazil. During 1983, most stations in north-east Brazil measured less than half of their normal rainfall amounts for that season, whereas the opposite was true during 1984.

Half-monthly values of sea-level pressure were substantially lower over the entire South Atlantic during 1984 in comparison with corresponding periods during 1982-83 (not shown). The reduction in surface pressure is consistent with the decreased strength of the trade winds. Sea-level pressure in the eastern tropical Atlantic returned to pre-1984 levels by September-November 1984. However, in the western tropical Atlantic, sea-level pressure remained lower than that during 1982-83 until June 1985.

The temporal and spatial evolution of the variations in ocean surface temperature and atmospheric circulation can be summarized as follows. Beginning in early 1984, sea surface temperature began to rise sharply across the entire equatorial strip, particularly to the south of the Equator. The warmest temperatures were observed along the Equator from March to May 1984, the season during which the equatorial Atlantic is normally warmest. Anomalies of roughly 1 °C in sea surface temperature persisted through the remainder of 1984 to the south of the Equator, while temperatures were normal or slightly below normal to the north of 5 °N. Although temperatures in the eastern equatorial ocean returned to near normal by early 1985, abovenormal temperatures remained in the western Atlantic until June 1985.

The atmospheric circulation over the tropical Atlantic during early 1983 was in a highly perturbed state, with higher pressures than normal, stronger surface trade winds, a weakened and northward-displaced ITCZ, and drought over north-east Brazil. As the surface temperatures in the equatorial Atlantic were close to normal during this period, it is unlikely that this anomalous atmospheric circulation was forced from below. Concurrent with the anomalous circulation over the Atlantic, an extreme warm phase of ENSO was observed over the equatorial Pacific. As the low-frequency fluctuations of the tropical atmosphere are highly coupled over long distances, it is plausible that the anomalous conditions over the Atlantic were a remote readjustment of the tropical circulation to the unusually intense convection and rising motion over the eastern equatorial Pacific. Possible links between the warm phase of ENSO in the Pacific and weakening of the Atlantic ITCZ and drought in north-east Brazil have been discussed elsewhere²⁵.

During the period from November 1983 to January 1984, the surface trade-wind and surface pressure fields weakened. The reduction in surface wind stress led to alterations in the circulation and thermal fields of the equatorial Atlantic. As sea surface temperatures rose during early 1984, the Atlantic ITCZ shifted southwards and remained near and to the south of the Equator in the vicinity of the warmest sea surface temperature (>27 °C) until May. The anomalous pattern of near-normal sea surface temperatures to the south of the Equator and below-normal temperatures to the north of the Equator has been linked before to abundant rainfall in north-east Brazil and drought over the sub-Sahel regions of Africa^{26,27}.

Although surface pressures and surface trade winds increased perceptibly over the eastern Atlantic and north of the Equator towards the end of 1984, the ITCZ again migrated south of the

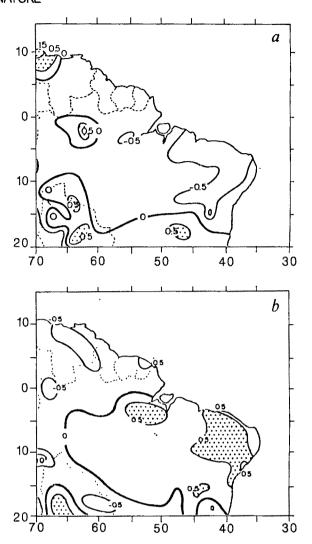

Fig. 3 Normalized precipitation deviations over north-east Brazil during a, March-May 1983 and b, March-May 1984. Values are calculated by determining the precipitation deviations from the mean and then dividing by the mean. The contour interval (in non-dimensional units) is 0.5; stippling indicates regions where seasonal rainfall totals were >0.5 of the seasonal mean.

Equator during February-May 1985 in the western Atlantic. This led to another season with above-normal rainfall in northeast Brazil. Sea surface temperatures gradually returned to near normal by the end of May 1985 in the equatorial Atlantic, and rainfall in sub-Sahel regions of Africa during the 1985 rainy season was much more plentiful than that during the previous two years.

The atmospheric circulation observed during the warm 1984 Atlantic event has many similarities to the warm 1983 ENSO event over the Pacific. The weakened trade winds, southward displacement of the ITCZ and enhanced equatorial convection are also features common to warm events in both the Atlantic and Pacific regions. However, several features are distinctly different. A major component of the warm Pacific event is the east-west shift of convection from the maritime continent towards the dateline and 'see-saw' of surface pressure, with lower pressures in the southeastern Pacific and higher pressures over the maritime continent¹⁻³. In contrast, the observed changes in cloudiness over the Atlantic were oriented primarily meridionally; convective activity over the Amazon basin exhibited little east-west movement during 1984 and pressures were reduced nearly uniformly across the southern Atlantic. Furthermore, the magnitude of the circulation changes in the Atlantic sector are

considerably weaker (roughly one half to one third) than those during the 1983 Pacific warm event and even slightly weaker than those during other such Pacific warm events, for example, those of 1972 and 1957.

The development of an unusually warm equatorial Atlantic, relaxed trade winds, and southward-displaced ITCZ are consistent with current theories on air/sea interaction over equatorial oceans. However, the conditions over the Atlantic during 1983-84 constitute an extreme event, much like the extreme nature of the 1982-83 warm event in the Pacific.

Influence of the Atlantic, Pacific and Indian Oceans on Sahel rainfall

T. N. Palmer

Meterological Office, Bracknell, Berkshire RG12 2SZ, UK

Folland et al. have reported that persistently dry and wet periods of several years in the Sahel have been accompanied by global-scale patterns of sea-surface temperature (SST) anomaly. They also demonstrated that the response of a general circulation model (GCM) of the atmosphere to an observed composite SST difference field between a number of such dry and wet periods showed substantial reduction in Sahel rainfall compared with values from a simulation with climatological SSTs. I examine here the same model's response to the individual components of the composite SST difference field in the Atlantic, Pacific and Indian Oceans. It is found that over the western Sahel, the Atlantic and Pacific fields have a comparable effect in reducing rainfall whereas the Indian Ocean field produces a slight enhancement. Results suggest that, over the eastern Sahel, the Indian Ocean has the dominant role in reducing rainfall.

Figure 1 shows the worldwide SST difference field between the five driest and five wettest years in the Sahel after 1949 and is discussed in more detail in ref. 1. Note that whilst this field

does represent differences between extreme years, values in the South Atlantic are not as large as anomalies (>2 K) observed during the exceptional warm event of 1984 (ref. 2). Similarly, values over the east Pacific are not as large as observed anomalies following the 1982/83 El Niño event³.

Results were obtained from several 180-day fixed July integrations of the Meteorological Office 11-layer GCM4 using the full difference field in Fig. 1, and its components in the three principal oceans. The integrations are identified as follows. The control integration has fixed climatological average July SSTs, and the anomaly integration (TOT) has the full field in Fig. 1 added to these values. Integrations ATL, PAC and IND have only those SSTs in Fig. 1 from the Atlantic, Pacific and Indian Oceans respectively, added to climatological values (see ref.) for a description of rainfall and low level moisture flux in the control integration).

Figure 2 shows 180-day mean-rainfall difference fields between the four anomaly integrations and the control. As discussed in ref. 1, in TOT (Fig. 2a) there is a coherent and substantial reduction in rainfall across the Atlantic and the Sahel, by up to 50% of the model's climatological mean. For integration ATL (Fig. 2b), the pattern of rainfall reduction over the Atlantic and the Western Sahel is similar to, but ~30% weaker than, that for integration TOT. Over the eastern Sahel, the reduction in rainfall is much less substantial in ATL.

For integration PAC, surprisingly at first sight, there is a similar pattern of rainfall reduction to that in TOT and ATL. Over the Atlantic, values are smaller than in ATL, and the rainfall enhancement to the south is absent. However, inland, over the Sahel, rainfall reduction seems to be larger than that in ATL

Results from IND are different. Inland, over the western and central Sahel, an enhancement in rainfall of over 1 mm per day is apparent. Further east, over Sudan and northern Ethiopia, there is a decrease in rainfall by up to 50% of climatological values. Finally, over the western Indian Ocean itself, values are strongly enhanced. (Although not shown, rainfall over the eastern Indian Ocean is also increased.)

An assessment of whether these rainfall anomalies are significant was made by calculating a t-variant from the six pairs of non-overlapping 30-day mean values of the control and anomaly integrations. If the conditions of the t-test were satisfied, then anomalies with |t| > 2 would be accepted at about the 7% significance level, using a two-sided test. t-Values with magnitude >2 shown stippled in Fig. 2. The reduction in rainfall across the Atlantic and into the extreme western Sahel is extremely-reproducible for experiment TOT whilst values of t are smaller in this region for ATL and, except for a small neighbourhood of the West African coast, t < 2 in PAC. In experiment IND, the increase in rainfall over the Indian Ocean is significant, as is the principal area of decrease over Sudan. In TOT, and more so in ATL, the increase in rainfall over north-east Brazil appears to be highly reproducible (although the northern summer is not the main rainy season in this area).

The addition of the SST anomaly in ATL reduces the meridional gradient of Atlantic SST just south of the intertropical convergence zone (ITCZ). As a result, the Atlantic Hadley cell south of the ITCZ is weakened and, as Fig. 3 shows, the low-level south-east Trade Winds are weakened. The flux of moisture into the ITCZ is reduced, producing less latent heating there, consistent with the weaker Hadley cell.

Whilst the main change in precipitation occurs over the Atlantic, Fig. 3a shows that reduction in low-level flow into the ITCZ also reduces the south-west monsoon flow into the western

As mentioned above, the composite positive SST anomaly in Fig. 1 is considerably weaker, particularly in the Gulf of Guinea, than SST anomalies observed during the exceptional warming of 1984. Hence, it is very likely that a more marked weakening of the south-west monsoon flow into the western Sahel would

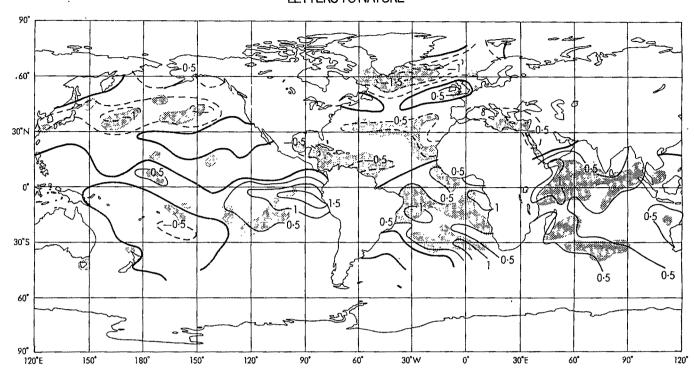

Fig. 1 SST for July to September. Average of 1972, 1973, 1982, 1983, 1984 (dry years) relative to average of 1950, 1952, 1953, 1954, 1958 (wet years). Contour interval, 0.5 °C. Shaded areas are different from zero at the 90% level of significance according to a *t*-test.

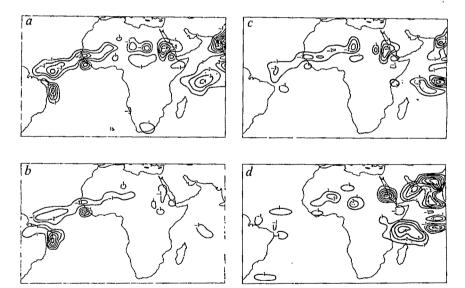

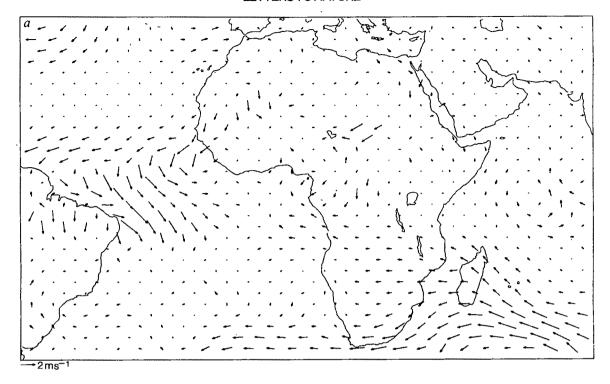

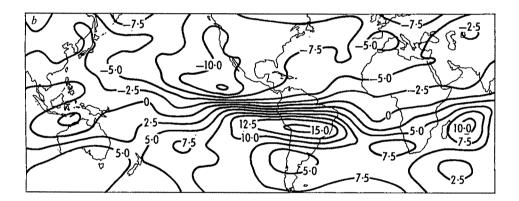

Fig. 2 Rainfall anomaly (relative to control integration) for experiment with: a, Full SST anomaly in Fig. 1 (TOT); b, Atlantic portion of Fig. 1 only (ATL); c, Pacific portion of Fig. 1 only (PAC); d, Indian Ocean portion of Fig. 1 only (IND). Contour interval, 1 mm per day. Stippling indicates areas where the magnitude of the t-variate exceeds 2.

have resulted if the 1984 SST anomalies had been used in place of those in Fig. 1. We hope to test this speculation in a future integration

Whilst the SST anomaly field in Fig. 1 has negative values over 1 K in the north Pacific, the principal influence of SST anomalies in PAC on rainfall is over the tropical Pacific. With water at 28 °C or warmer extending across most of the tropical Pacific north of the Equator in the climatological normal, the anomaly near the dateline in Fig. 1 produces a substantial increase up to 10 mm per day over the central and west Pacific, whilst anomalies west of Central America (which weaken the meridional SST gradient there) are associated with a reduction of the maximum of rainfall west of Mexico by up to 10 mm per day. Previous GCM studies with El Niño SST anomalies 5 have

shown that enhanced latent heat release in the central equatorial Pacific excites an atmospheric Kelvin wave which can propagate across the Atlantic and Africa without complete dissipation. As a result the equatorial upper troposphere is warmed, geopotential height is raised and anomalous equatorial westerlies are produced, in agreement with results from thermally forced linear equatorial β -plane models⁶. Figure 3b shows the 250-mbar streamfunction anomaly from PAC. The north-to-south gradient indicates that the anomalous non-divergent wind in the tropics at 250 mbar indeed has a westerly component, strongest over the east Pacific, but extending over the Atlantic and Africa. The wind anomalies have a baroclinic vertical structure near the ITCZ over the Pacific, Atlantic and Sahel, with an easterly component at low levels.

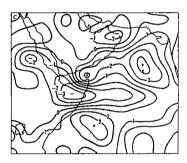

Fig. 3 a, 950-mbar wind anomaly for experiment ATL; b, 250-mbar streamfunction anomaly (×10⁶ m² s⁻¹) for PAC; c, 250-mbar divergence anomaly $(\times 10^{-6} \,\mathrm{s}^{-1})$ for IND.

This again reduces the south-west monsoon flow into the western Sahel, and thereby the supply of moisture for precipitation. The fact that there is no significant increase in rainfall over the Atlantic south of the ITCZ in PAC is consistent with the divergent circulation anomalies being mainly east/west oriented ('Walker cell') rather than north/south ('Hadley cell') as in ATL.

Results from IND are more easily understood. In Fig. 2d, there was substantial enhancement of rainfall over the Indian Ocean; Figure 3c shows anomalous divergence at 250 mbar associated with this enhancement. The correspondence between divergence and rainfall arises from the local thermodynamic balance in the tropics7 between adiabatic cooling by vertical motion and latent heat release. The main area of descent required by mass continuity appears to be located over Ethiopia and Somalia, consistent with the rainfall decrease there. The anomalous low-level wind in this region (not shown) flows from land to ocean, similar to Fig. 3a for ATL.

The tropical Atlantic therefore has a role in modulating rainfall over the Sahel, and was probably paramount during the exceptional 1984 season. On the other hand, effects from either the Pacific or Indian Ocean cannot be ignored. Hence, a com-

plete understanding of variability of rainfall in the Sahel involves consideration of the entire tropical circulation. As such, these model results are in agreement with the observational correlations between worldwide SST and Sahel rainfall, discussed by Folland et al.1.

However, results from the t-test also show that over most of the Sahel, rainfall anomalies were quite variable. On the other hand, a stronger and more significant response to SST anomalies in this area might be expected if coupling between rainfall, ground reflectivity and soil moisture capacity4 were built into the model.

C. K. Folland and D. E. Parker supplied the SST data shown in Fig. 1. I also thank them for many useful discussions.

River dynamics and the diversity of Amazon lowland forest

Jukka Salo*, Risto Kalliola*, Ilmari Häkkinen*, Yrjö Mäkinen*, Pekka Niemelä*, Maarit Puhakka* & Phyllis D. Coley†

* Department of Biology, University of Turku, SF-20500 Turku, Finland † Department of Biology, University of Utah, Salt Lake City, Utah 84112, USA

We suggest here that large-scale natural forest disturbance and primary succession in the lowland rainforests of the Peruvian Amazon is caused by lateral erosion and channel changes of meandering rivers. Our results indicate that in the upper Amazon region, primary succession on newly deposited riverine soils is a major mode of forest regeneration. Landsat imagery analyses show that 26.6% of the modern lowland forest has characteristics of recent erosional and depositional activity; 12.0% of the Peruvian lowland forest is in successional stages along rivers. This successional development is used to classify the western Amazon rainforests according to their geomorphological erosion-deposition pattern. We also propose that by causing high site turnover, disturbance and variation in forest structure, the river dynamics may be a major factor creating and maintaining the high betweenhabitat (β -type) species diversity characterizing the upper Amazon¹

The degree of forest disturbance caused by river-channel erosion was studied in $>0.5\times10^6\,\mathrm{km^2}$ of the Peruvian Amazon by using analyses of Landsat MSS (multi-spectral scanner) images (visual analysis). The disturbance is caused by the lateral erosion and channel changes of the meandering and braided white-water rivers (rich in fine suspended inorganic solids; see refs 2–7) of the western periphery of the Amazon region^{8–12}. Patterns of primary succession on newly deposited riverine soils were examined in more detail along the Rio Madre de Dios and Rio de los Amigos in the Madre de Dios region of southeastern Peru in 1982. The work was continued at the Cocha Cashu biological station at Manú National Park in 1983–86.

Twenty-two Landsat images of the Peruvian headwater region were surveyed for indications of former riverine erosion (Fig. 1, Table 1). In the analyses, we defined three erosional-depositional formations: (1) present floodplain formation, (2) previous floodplain formation, unquestionable floodplain origin; and (3) forests on denuded soils, which includes all the forests beyond the present or previous floodplains (these are probably also of former floodplain/lacustrine origin^{13,14}, derived from the depositional processes described here).

(1) Forests on the present floodplains are the areas most recently subjected to lateral erosion and channel migration. They were detected on the images by delimiting the areas covered by the present meander plains, which were defined as the areas containing the present meanders and the most recent channel cutoffs and oxbow lakes. This area, which has recently undergone several cycles of complete lateral erosion, may be further divided into two distinct types: sequential successional forest and mosaic forest (Fig. 2). Active deposition occurs on the inside of the meander bends, by point bar accretion, and with time meander migration has produced a series of meander scrolls; these form a sequence of ridges running parallel to the river course, on which a sequential primary forest succession takes place. The sequential succession proceeds undisturbed until the migrating river channel cuts the meander from a different angle.

According to the repetitive nature of river dynamics, the migration of the river channel course creates a mosaic of successional forests within the present meander plain. The mosaic forest is composed of patches of differentially aged sequential

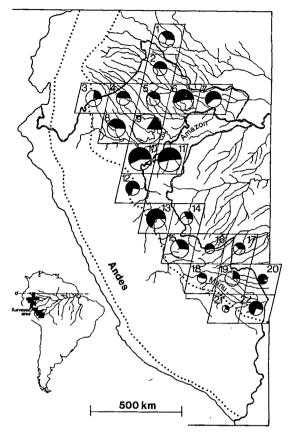

Fig. 1 The distribution and areas of riverine disturbance in the Peruvian Amazon basin. Each of the 22 squares represents one Landsat image (182.5×182.5 km). The sizes of the circles give the area (km²) of total floodplain (see text and Table 1 for details), representing the disturbed area covered by sequential floodplain generations. The black sectors represent the area of the forests on the present floodplains (sequential successional and mosaic forests). The white sectors show the area of the forests on the previous floodplains, indicating transitional forest. Inset, orientation map.

successional forests and patches of forests originating from a succession on the sites of former oxbow lakes. The annual floods further modify the mosaic pattern. The total area covered by the present floodplains is 12.0% of the area analysed.

(2) The area covered by former floodplain formations was defined by identifying the areas of flat surface topography without the convex-concave morphology¹⁵ (indicating surface erosion; for details see refs 16-19) characteristic of the upper Amazon forests on the oldest alluvium of diverse nature. The surface processes acting on Amazon abandoned floodplains change from depositional to erosional with increasing age²⁰. The area characterized by lack of the convex-concave topography is also scattered with isolated oxbow lakes, thus confirming the fluvial/floodplain origin of this formation. We believe that the successional status of forests growing on the soils of previous floodplains is transitional, as the mode of forest regeneration takes place increasingly through secondary succession, promoted by light gaps.

Previous floodplain formations cover 14.6% of the area analysed. The geomorphology of the old floodplains remains highly heterogeneous and is composed of a mosaic of abandoned river channels, oxbow lakes and sedimentary beds of different ages. This heterogeneity gives rise to densely packed plant communities of different ages and origin. In contrast to forests under the influence of present floodplains, older areas of floodplain are scattered throughout the analysed area, indicating major channel changes in the recent history of the western Amazon river system.

(3) The area beyond the present and previous floodplain

Forests on the present floodplains are undergoing primary and early succession on newly deposited riverine soils. The present floodplain formation is composed of the sequential successional and mosaic forests. Forests on the previous floodplains represent the area covered by a series of older floodplain formations (transitional forest). The analyses are based on visual analysis of 1:10⁶ Landsat images MSS 7, except scenes 007.63 and 007-65, which are MSS 6.

formations has the convex-concave surface erosion pattern. The origin and geomorphology of these areas is unknown, but the erosion pattern is found on both floodplain and lacustrine (Belterra clay type) deposits. As the processes operating on the floodplains change towards erosional, the topography becomes similar to that of the areas of convex-concave relief^{15,20} (see Fig. 2).

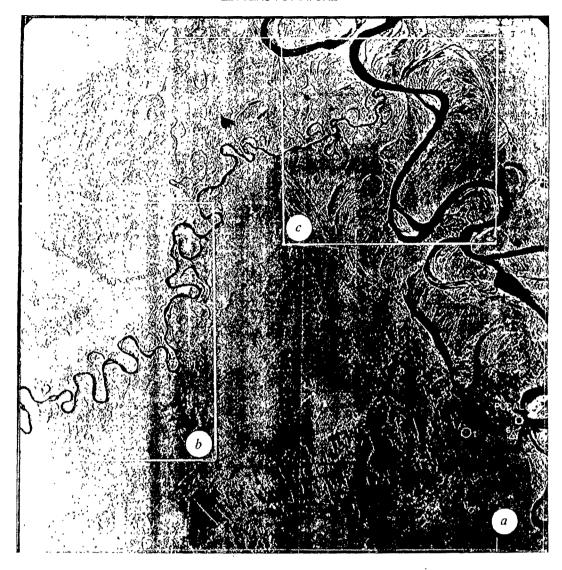

In the western Amazon, the structure of the denuded topmost sedimentary layer has been only locally surveyed $^{8-12,21-24}$. However, there is good reason to believe that after the glacial periods of the Quaternary, the Andean tills, re-worked by rivers, formed a belt of highly heterogenous sedimentary beds in front of the foothills of the Eastern Cordillera 24 . In Peru and Bolivia, the uppermost sedimentary bed, called the Iñapari Formation, overlies the Tertiary red beds $^{25-28}$, especially at sites of high river erosion banks ('cerros'). Recent radiocarbon dates of four samples collected from three 35-m eroding channel banks along the Rio Acre, Bolivia, show that these sediments were deposited between $5,575\pm105$ and $10,085\pm150$ yr BP (ref. 28). These data indicate the youth of the Iñapari Formation, although the stratigraphy of the samples may merely reflect a local sedimentation pattern within the Rio Acre region.

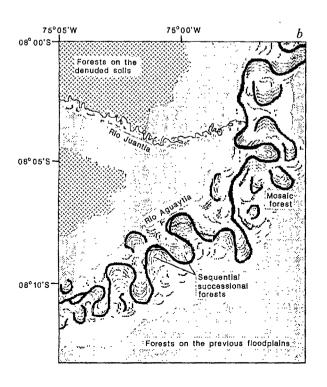

To evaluate the rate of forest regeneration within the areas of sequential successional and mosaic forests, an analysis of a 70-km section of the Rio Manú from the Cocha Cashu station (11°53′ S, 71°24′ W; 350 m above sea level) to Boca Manú (12°15′ S, 70°55′ W, 320 m a.s.l.) was carried out. We compared 1962-63 aerial photographs with a 1976 Landsat image (276296-135752-7). The mean lateral erosion rate of the meander bends during the 13-yr period was 12 m yr⁻¹. During this period, the total area of newly created depositional land subject to primary succession was 12.0 km², representing 3.7% of the present flood-plain formation area (325 km²).

The typical pattern of riparian primary succession (sequential successional forest) is summarized in Fig. 3, where characteristics of the successional meander forest which is common along most of the western Amazon lowland rivers²⁹ are emphasized. Extreme zonation of vegetation occurs during the early phases of succession (up to the Ficus-Cedrela zone³⁰). This zonation is initially created by the instability of the youngest point bar deposits ('beaches') on the inner curve of the meander (see Fig. 3 for details). Tessaria integrifolia (Asteraceae) is the first pioneer tree to appear, because its seedlings can tolerate the arid and unshaded conditions of this environment. Invasion by other successional trees is possible only after modification of the microclimate by Tessaria. At this stage, competition between species may further influence the zonation pattern.

The traditional view of the Amazon rainforests has emphasized stability, with the dominant mode of forest regeneration occurring in light gaps created by fallen trees. Estimated tree-fall frequencies from several lowland tropical forests indicate that 3-5% of the forest is in the first 5 years of regeneration in light gaps³¹⁻³³. Our results show that the lateral erosion and channel changes of rivers repeatedly disturb all types of forest in the western Amazon lowlands, and thus create a mosaic of forests with higher age heterogeneity than could have resulted from regeneration in light gaps alone. Also, the nature of forest regeneration is fundamentally different in these two processes. The erosional disturbance is much more severe than disturbances caused by tree-falls. Regeneration on newly exposed fluvial deposits ('beaches') must start with the earliest phases of primary succession. Regeneration in tree-falls is due to growth of established saplings or of a well-developed seed bank. Finally, areas of riparian succession occur in long, continuous and dynamic strips along recent and abandoned river channels. This spatial

^{*} In the analysis, Andean rifts and areas shaded by clouds or other turbulence are excluded. The total area of each image is 33,300 km²

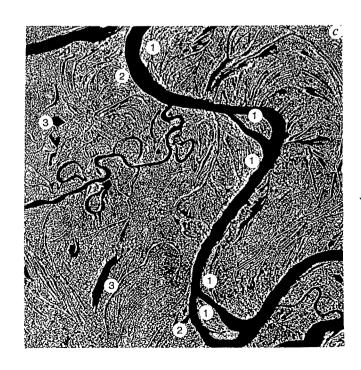

Fig. 2 (Left) a, Side-looking airborne radar (SLAR) image of the floodplain mosaic formed by the white-water river Ucayali at Pucallpa, Perú (8°15' S, 74°40' W). b, Simplified map of the forest disturbance site in a. The sequential successional forest is created on both sides of the meandering rivers Aguaytía and Juantía. As the meandering proceeds, the sequential successional forest is cut from different angles and a mosaic forest structure is created. During the annual flood cycle, sedimentation modifies the sequential meander scroll topography towards the flat topography of the former floodplain area. The previous floodplains are generally at a topographically higher level than the present floodplains. The denuded forest areas (upper left corner) representing the surface erosion relief pattern (convex-concave morphology) are being laterally eroded by the Rio Juantía. The transitional forest (lower right corner) is developing towards the denuded pattern. c, Detailed map of forest ground development. 1, Sites of intense primary succession at meander points leading to sequential successional forest. 2, Mosaic and transitional forest subject to lateral erosion at the outer curve of the meanders. 3, Isolated oxbow lakes. Based on ONERN SLAR image SC-18 3.A.

distribution differs markedly from the scattered distribution of light gaps.

We also propose that forest disturbance due to modern and past river dynamics is partially responsible for the high biological diversity in the upper Amazon basin^{34–36}, for several reasons. First, many distinct habitats are generated by erosional and depositional activity of rivers. As the forest succession and river bank erosion proceed, a mosaic of forests of different ages and on different soils is created (Fig. 2). A good example of this is the species richness of the Tambopata and Manú reserves in southeastern Peru^{30,36}, both of which are located at sites which have been, and still are, modified by relatively small meandering rivers (Rio Tambopata and Rio Manú, respectively) causing closely packed, small-scale habitat mosaics. Second, the habitats are highly stable in species composition and are relatively shortlived, so there is insufficient time for competitive exclusion³ Finally, the floodplains may differ profoundly in water and soil chemistry, mode of alluvial sedimentation, and case-historical bio-geographical events.

The river dynamics may also represent a mechanism leading to a pattern of equal allopatric speciation, as has been proposed to operate in the context of the Pleistocene refuges³⁸. The Pleistocene refuge theory states that the basis for the prevailing high species richness of the Amazon lowlands was laid down during the arid phases of the Pleistocene³⁹. During this time, the continuous forest was repeatedly fragmented into savannah-bordered isolates. Owing to the dynamic nature of the topmost sedimentary layer in the western Amazon, both floodplains separated by old denuded-soil forests and the denuded-soil

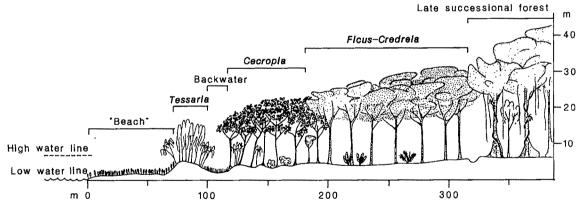

Fig. 3 Riparian succession in the sequential successional forest next to the Rio Manú at the Cocha Cashu biological station (11°53' S, 71°24' W). The scheme is a simplified transect of the Cocha Cashu meander loop from the point (left) towards the neck. The 'beach' is created by the deposition of river sediment on the point bar of the meander bank. The dominating species (~99%) is Tessaria integrifolia (Asteraceae). The persistence of Tessaria seedlings depends on the stability of the 'beach', successful colonization reaching maturity is expected to take place only once in a 4-yr period. Other primary successional species include: Baccharis salicifolia (Asteraceae), Cassia reticulata (Leguminosae), Cyperus spp. (Cyperaceae), Ipomoea spp. (Convolvulaceae), Ochroma lagopus (Bombacaceae) and Panicum spp. (Poaceae). The Tessaria-Gynerium zone is situated on the youngest point bar, the topography of which is accentuated by the deposition of sandy river sediment during the annual flooding of the river, predominantly during December-April. In the middle part of the zone, stands of reproductive Tessaria of equal age predominate. Both sides of the zone are dominated by Gynerium sagittatum (Poaceae). Gradually, Tessaria is replaced by Gynerium. The zone harbours seedlings of Cecropia cf. tessmannii (Moraceae), Cedrela odorata (Meliaceae) and Ficus insipida (Moraceae). The 10-30-m-wide backwater depression marks the previous position of the river channel, before accretion of the youngest point bar. During the high-water period the depression is often used as a secondary channel, or chute, as a result of turbulence in the flood waters. The backwater depressions run parallel to the river and their number in meander loops varies according to the local turbulence patterns. In the middle of the backwater depression runs a belt of Hymenachne donacifolia (Poaceae). The edges of backwater depressions are invaded by young Cecropia trees. As the backwater belt becomes subject to lesser annual flooding, the Cecropia forms a closed canopy over the belt. Before this, the stagnant water prevents the invasion of other trees or Gynerium. The Cecropia zone is located on the older meander scrolls with intermediate former backwater depressions. The dominating soil type is still fluvial sand. The forest is dominated by Cecropia tessmannii, forming an open canopy at 14-18 m. The gaps in the canopy promote patches of declining Gynerium. The gaps are filled by Caseara sp. (Flacourtiaceae), Cedrela odorata, Erythrina spp. (Leguminosae), Ficus insipida, Guarea sp. (Meliaceae) and Sapium sp. (Euphorbiaceae). The understorey includes members of the families Euphorbiaceae, Melastomataceae, Piperaceae and Acanthaceae. The topography in the Ficus-Cedrela zone is more gentle than in the previous stages due to the sedimentation of alluvial silt which is deposited annually during the flooding period, forming a layer above the riverine sands of the meander scrolls and chutes. The zonation characterizing the vegetation in the previous phases is diminishing. The closed forest canopy is formed mainly by fruiting Ficus insipida and Cedrela odorata. The understorey is dominated by thick growth of Heliconia spp. (Musaceae). The Ficus-Cedrela forest is characterized as the first zone containing palms. The topography of the late successional forest (mosaic forest) is generally flat, with minor depressions and gentle hills. The forest structure is further diversified by autogenic succession promoted by light gaps.

forests themselves may act as isolates within which biological differentiation can occur. There is a growing body of evidence that the number of species confined only to floodplain or denuded-soil forests is exceptionally high in the Amazon⁴ If the rivers repeatedly form new major floodplains and abandon old ones, subsequent secondary contact of formerly separated river systems, floodplains and denuded-soil forests may lead to species dynamics similar to the refuge pattern.

The ecological consequences of river dynamics and riparian primary succession also have profound implications for the conservation policies of the Amazon. As a major part of the forest has gone through riparian succession, the first phases of succession may be essential in determining the structure of the later successional forest. Conservation programmes based solely on the Pleistocene refuge theory may not preserve the present dynamic mechanism underlying the maintenance of high species diversity.

Normal maturation involves systematic changes in binocular visual connections in Xenopus laevis

S. Grant* & M. J. Keating†

National Institute for Medical Research, Mill Hill, London NW7 1AA, UK

Systematic changes in neuronal connections have been observed during the development of many vertebrate neuronal systems. These changes have usually involved a refinement from an initial exuberance of connections¹⁻⁴ or a response to some experimental perturbation⁵⁻⁸. Here we report on a system of neuronal connections, which, during a protracted developmental period, undergo ordered changes in response to normally occurring changes in functional requirements. In the frog Xenopus laevis, interocular alignment changes markedly during late larval and post-metamorphic life, producing a progressive enlargement of the binocular portion of the visual field^{9,10}. An intertectal system links the two mid-brain optic tecta and is concerned with the neural representation of binocular visual space. In the adult animal, connections in this system link corresponding points (points receiving information from one locus of binocular visual space) on the two tecta. Changes in eye position with development, however, change the set of corresponding points. Therefore, if the intertectal connections link corresponding tectal points throughout development, they must undergo an ordered change with time. We present electrophysiological evidence that the intertectal connections do, indeed, undergo such changes in response to changes in eye alignment, and that the changes are major.

In the late larval Xenopus the two eyes face laterally and there is no fronto-superior binocular visual field. As metamorphic climax approaches, changes in skull shape produce frontal and dorsal migration of the two eyes. This movement persists into post-metamorphic and adult life. Optical methods were used to determine the relative alignment of the two optic axes and the extent of the two monocular visual fields^{9,10}. These measurements indicated that the interocular angle changes from 160° at stage 60 (ref. 11), the onset of metamorphic climax, to 50° in adult life. The monocular visual field remains relatively constant between 195° and 200° throughout this period. The binocular visual field (the area of overlap of the two monocular visual fields) thus increases from ~35° at stage 60 to 45° at stage 62, 100° at stage 66 (the completion of metamorphic climax) and ~150° in adult life. This growth of the binocular visual field with age is plotted, on right eye-centred coordinates, in Fig. 1.

In the adult each optic tectum receives two projections of binocular visual space, one through each eye. The contralateral visuotectal projection is the product of the direct retinal fibre input from an eye to its contralateral optic tectum. The system of intertectal connections conveys visual information from the contralateral to the ipsilateral tectum and thus underlies the ipsilateral visuotectal projection 12-18. Figure 2 shows the four visuotectal projections in a normal adult. The adult ipsilateral visuotectal projection displays several characteristics: it arises from the full extent of the binocular visual field, it is topographically ordered, and is in register with the contralateral visuotectal projection to that optic tectum. Figure 2 legend outlines the analysis by which the pattern of functional intertectal connections may be determined from the visuotectal projections.

To determine whether the pattern of intertectal connections changes during normal development, visuotectal projections were mapped electrophysiologically in 52 animals from stage

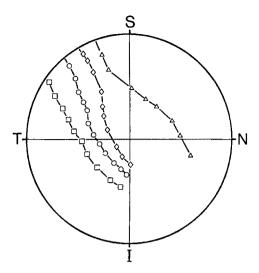

Fig. 1 Developmental changes in the extent of the binocular visual field in Xenopus. For these measurements, animals were placed at the centre of an Aimark projection perimeter (radius 33 cm) with the optic axis of the right eye aligned with the fixation point of the perimeter. The larger circle represents the visual field of the right eye, subtending some 200° of solid angle about the origin of this polar coordinate representation of visual space. The animal is thus positioned such that the right eye is looking out from the surface of the page. N, T, S and I are the nasal, temporal, superior and inferior poles of the visual field of the right eye. Reversible ophthalmoscopic methods used to determine the boundaries of the two monocular visual fields were those described by Grobstein and Comer⁹. The symbols represent the optically-determined naso-superior boundary of the visual field of the left eye at different developmental stages. The results are presented as mean observations from animals at stage 62 (\triangle , n=2), stage 66 (\diamondsuit , n=3), 3 months after metamorphosis (O, n=3) and adulthood $(\Box, n=4)$. Neither the range nor standard error bars are shown as they were of the same order of size as the symbols. The binocular visual field at any developmental stage is the overlap of the two monocular visual fields and is that area between the symbols and the naso-superior periphery of the visual field of the right eye.

Table 1 Degree of registration of ipsilateral and contralateral visuotectal projections to one tectum at different developmental ages

Age	Nasotemporal disparity (deg.)	Superoinferior disparity (deg.)
Stage $60-64 \ (n=107)$	1.5 ± 12.6	3.2 ± 10.0
Stage 66 $(n = 129)$	1.3 ± 10.0	0.3 ± 9.7
$3MAM \qquad (n=121)$	3.2 ± 10.8	0.2 ± 9.4
12MAM (n = 165)	0.8 ± 12.8	0.5 ± 7.4
Adult $(n=137)$	0.3 ± 9.9	0.4 ± 7.9

Values are mean ± s.d. MAM, months after metamorphosis. n, Number of electrode penetrations.

60 to adulthood. Detailed maps permitting such analysis were obtained in animals at stage 60 (2), stage 62 (4), stage 64 (5), stage 66 (10), and post-metamorphically at 2 weeks (8), 6 weeks (2), 3 months (10), 1 yr (7) and adulthood (4). Figure 3 shows representative results from animals at stages 62 and 66 and 3 months after metamorphosis. We found that, at all developmental ages studied, the ipsilateral visuotectal projection arose only from the binocular portion of the visual field and effectively occupied the entire binocular visual space then existing. This projection thus increased in size with age as the binocular visual field enlarged. There was a corresponding increase in the proportion of the tectal surface occupied by the ipsilateral visuotectal projection.

Table 1 provides data on the degree of registration between the ipsilateral and contralateral visuotectal projections to one

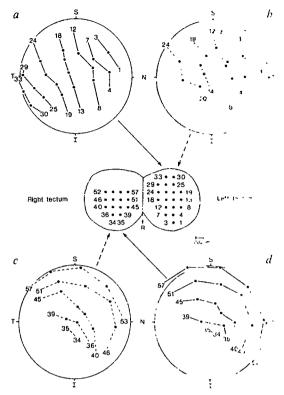

Fig. 2 The contralateral and ipsilateral visuotectal projections in a normal adult Xenopus. This animal, anaesthetized with MS 222 (ethyl m-aminobenzoate; Sigma) and subjected to partial craniotomy, was placed in an Aimark projection perimeter with its right eye centred (see Fig. 1 legend). The diagrams of the optic tecta show their outlines, transposed from a photograph of the dorsal surface, upon which a 100-µm grid was superimposed. Rostral is indicated by the direction of the midline arrow labelled R. Numbers and intermediate dots on the tectal diagram represent the sites of vertical microelectrode penetrations. Large circles denote perimetric chart representations of the visual field, with the optic axis of the right eye centred on the fixation point of the perimeter as in Fig. 1. The animal was not moved within the coordinate frame during the recording session, thus the four chart representations plot identical areas of visual space. For each microelectrode position the centre of the region in visual space, stimulation of which produced evoked unitary potentials at that electrode site, when viewed by either the right or the left eye, is indicated by the corresponding number of intermediate dots on the relevant chart representation. a, The contralateral visuotectal projection through the right eye; b, the ipsilateral visuotectal projection through the left eye; c, ipsilateral visuotectal projection through the right eye; d, contralateral visuotectal projection through the left eye. The indirect nature of the ipsilateral visuotectal pathway is denoted by the discontinuous lines within and from the visual field representations. N, T, S and I are the nasal, temporal, superior and inferior aspects of the visual field of the tested eye. Note that the two visual projections to each tectum are in register, for example, equivalent visual field positions 35 in c and d project through both right and left eyes to microelectrode position 35 in the right tectum. The pattern of intertectal connections may be derived from the visuotectal projections as follows: right tectal position 35 is receiving visual input from visual field position 35 through the contralateral left eye. This visual field position is identical to field position 21 which projects through the left eye to left tectal position 21. The presence of an ipsilateral visuotectal response at the left tectal position 21 indicates that visual information, conveyed from the left eye directly to right tectal position 35, has been relayed through the intertectal system to left tectal position 21. When this type of analysis is extended to other parts of the visuotectal projections through the left eye, it yields the overall pattern of intertectal connections relaying information from the right to the left tectum. Similar analysis of the visuotectal projections through the right eye to both tecta reveals the pattern of intertectal connections from the left to the right tectum. The latter are, in fact, the reciprocal of those from the right to the left tectum.

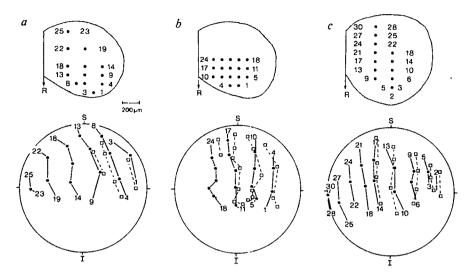

Fig. 3 Contralateral and ipsilateral visuotectal projections to the left tectum in representative animals at: a, stage 62; b, stage 66; and c, 3 months after metamorphosis. Conventions are essentially similar to those of Fig. 2, except that the two visuotectal projections are superimposed. The contralateral projections are represented by closed circles linked by continuous lines, the ipsilateral projections by open squares linked by dotted lines. Projections to the right optic tectum were also mapped but are not shown

tectum at various developmental ages. The nasotemporal and superoinferior disparities between the two visual field positions to one tectal locus were measured and the results grouped by developmental age. Apparently, there were no systematic disparities at any developmental age, indicating that throughout development the ipsilateral visuotectal projection through one eye was in register with the contralateral visuotectal projection through the other eye.

The patterns of intertectal connections at various stages of development from stage 60 to adulthood were determined from the visuotectal projections by the method outlined in Fig. 2 legend. To compare the connections at different developmental stages, it is necessary to know the nature of tectal growth during this period. We have recently reported¹⁰ the results of a detailed study on histogenetic and hypertrophic growth of both the retina and the tectum from stage 60 to adulthood. Summarizing the tectal results briefly, there was no significant tectal histogenesis during this period. From stage 60 until 3 months after metamorphosis there was little change in the linear dimensions of the tectum although these did increase thereafter. Tectal cell density counts indicated that this increase in tectal size was uniformly hypertrophic; this information was used to construct the diagram in Fig. 4, which shows the different points on the left optic tectum to which a given site near the rostral pole of the right optic tectum projects, via the intertectal system, at different developmental stages. When the ipsilateral visuotectal projection first appears at stage 60, the rostral pole of the right tectum is linked to a rostral region in the left tectum. As development proceeds through metamorphosis and juvenile life into adulthood, this same area of the right tectum is linked progressively to more caudal left tectal areas. Similar results are obtained if we consider other points on the right tectum participating in the intertectal system. With time, progressively more caudal right tectal areas are incorporated into the system, these project initially to rostral left tectal areas and are then displaced more caudally on the left tectum as new input arrives from the right tectum. The intertectal system itself is not a direct link but involves a synaptic relay in the nucleus isthmi¹⁴⁻¹⁸. Our present data do not allow us to determine which component(s) of the tecto-isthmo-tectal pathway is involved in this normal developmental plasticity. Other studies 17,19,20, however, suggest that it is the crossed isthmo-tectal projection that is the plastic component.

We conclude that the normal maturation of the intertectal system in *Xenopus laevis* is a highly plastic process. In response to the changing functional requirements presented by changing interocular alignment, the intertectal system undergoes a continuous and systematic change in its functional connections.

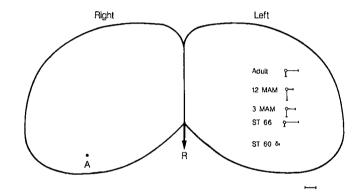

Fig. 4 Illustration of the changing intertectal connections during normal development in Xenopus. This diagram was constructed from patterns of intertectal connections derived, as explained in Fig. 2 legend, from animals of different developmental ages. For simplicity, the changing links of only one right tectal position (A) are shown. The diagram shows the positions on the left tectum which, at different stages of development, receive intertectal connections from the given position (A) near the rostral pole of the right tectum (MAM, months after metamorphosis; Ad, adult). As animals of different ages are involved in this analysis, allowance had to be made for tectal growth during this period (see text). The tectal diagrams represent tecta in adult animals. In plotting the results from younger animals on these tecta, the necessary corrections for tectal growth have been made. The open circles on the left tectum indicate the mean position for animals of that age (stage 60, n=2; stage 66, n=10; 3MAM, n=10; 12MAM, n=7; adult, n=4). The bars indicate the standard deviation in the rostro-caudal and medio-lateral tectal axes, except in the case of the two stage-60 animals, where they indicate the range. The rostro-caudal tectal positions of all age groups shown are statistically different from each other. Intertectal connections from the rostral region of the right tectum project, with age, to progressively more caudal positions on the left tectum. The converse is also true. As the normal intertectal projection is reciprocally symmetrical, this diagram also shows that, with age, intertectal connections from the left tectum to the rostral region of the right tectum arise from progressively more caudal tectal positions. Calibration bar, 200 μm.

The fact that the normal development of this system entails such continuous synaptic adjustments may explain why it is capable of responding with major readjustments to experimental perturbation of interocular alignment, as, for example, by early eye rotation 17,19,21-23. In both normal development and following eye rotation, the intertectal connections alter so as to link the new set of corresponding tectal points. Visual deprivation disrupts the normal development of the intertectal system 20,24,25

and prevents the readjustment of intertectal connections following eve rotation²⁴.

In the cat the first few months of postnatal life see a maturation of eye alignment²⁶⁻³¹ involving maturational changes in cortical and callosal systems associated with binocular vision3,31-33. These systems are also able to adjust following experimental alteration of eye alignment^{7,8,34-36}. It has been suggested that critical periods of experience-dependent development in both binocular visual³⁷⁻⁴⁰ and binaural auditory⁴¹ systems reflect a requirement for neuronal systems to adjust to growth-related changes in interocular or interaural geometry. In Xenopus the developmental changes in interocular geometry are particularly marked; the intertectal system in this species provides a clear demonstration that a neuronal system subserving binocular integration does, in fact, undergo extensive functional rewiring during normal maturation.

Measurement of the intracellular free calcium concentration in salamander rods

P. A. McNaughton, L. Cervetto* & B. J. Nunn

Physiological Laboratory, University of Cambridge, Downing St, Cambridge CB2 3EG, UK

Measurement of the free calcium concentration within a photoreceptor outer segment has been considered an important aim since the proposal by Hagins and Yoshikami^{1,2} that the primary event in phototransduction is a release of Ca2+ inside the cell. More recent evidence3-6 has cast doubt on the calcium hypothesis, and the observations of Yau and Nakatani⁷ and Matthews et al.⁶ suggest that the internal Ca2+ concentration ([Ca2+],) may decrease after a flash of light. In the present study we have measured [Ca2+], directly by using a new method for incorporating the Ca-sensitive photoprotein aequorin into an isolated rod. We report that the light response is accompanied by a decrease in [Ca²⁺]_i, caused by the closure of light-sensitive channels which are the main route for Ca2+ entry into the outer segment. Of the Ca2+ entering through light-sensitive channels, about 95% is sequestered by a rapid and reversible buffering mechanism. Calcium is removed from the cell by an electrogenic pump³ in which 3 Na⁺ ions are exchanged for each Ca²⁺; the pump is highly active and the free Ca2+ in the cell declines with a time constant of ~0.5 s after a flash of light.

A rod mechanically isolated from the retina of the tiger salamander, Ambystoma tigrinum, was drawn, inner segment first, into a suction pipette, leaving the outer segment projecting into a solution which could be rapidly changed⁴. A whole-cell recording pipette was sealed against the outer segment membrane, and the membrane was broken by suction or by a pulse of current^{6,8,9}. Aequorin was then ejected from a fine plastic pipe inserted as close as possible (~100 µm) to the mouth of the whole-cell pipette, and was allowed to diffuse into the rod outer segment (ROS). The whole-cell pipette was gently withdrawn after ~10 min; the membrane usually reseals, leaving the aequorin-loaded rod in the suction pipette. Rods were loaded

with up to 4×10^4 counts using our method, corresponding to $\sim 4 \times 10^6$ aequorin molecules in the cell.

In normal Ringer's, the calcium concentration in the ROS is below the limit of resolution of the present method, and no significant change in [Ca²⁺]; could be detected during the response to a flash of light. From the cell in which the best loading was obtained, an upper limit of 0.6 µM (at the 95% confidence level) could be set for the free calcium concentration both in the dark and at the plateau of the light response.

The calcium concentration can be increased to detectable levels by using the phosphodiesterase inhibitor IBMX (3isobutyl-1-methylxanthine) which increases the intracellular level of cyclic GMP and consequently opens light-sensitive channels^{5,10,11}. Figure 1 shows that when IBMX was applied to the outer segment the light-sensitive current increased, and a burst of light was recorded from the aequorin-loaded cell. If the exposure to IBMX was prolonged the light-sensitive current oscillated, and each current maximum was accompanied by a burst of aequorin light emission. These results are difficult to reconcile with the idea that intracellular Ca2+ acts directly to close light-sensitive channels, since the light-sensitive current and free [Ca²⁺], increase at the same time. A more likely explanation is that light-sensitive channels are permeable to Ca2 (for which there is other evidence^{3,4,12}) and that [Ca^{2*}], rises because of the increase in light-sensitive current in the presence of IBMX. The oscillatory response to IBMX application was not seen in unloaded rods, and must be connected with absorption of the aequorin light by the photosensitive mechanism of the rod itself.

The effects of a flash of light on [Ca²⁺]_i were investigated in the experiment shown in Fig. 2. As in Fig. 1, [Ca2+], was first increased to measurable levels by applying IBMX, and a bright flash was then delivered at the peak of the increase in current (Fig. 2, trace 1). The flash caused a delayed decline in [Ca²⁺], and the free calcium level after the flash at no time exceeded that observed in the absence of a flash. A small, slowly declining inward current is visible at the plateau of the light response (marked with a triangle in trace 1 of Fig. 2a). This current has been attributed to the operation of a light-insensitive electrogenic Na/Ca exchange which reduces the Ca²⁺ level within the cell after a flash of light^{3,7,10}. Figure 2c supports this interpretation as the time course of the decrease in [Ca²⁺], correlates with the integral of this 'pumping current'.

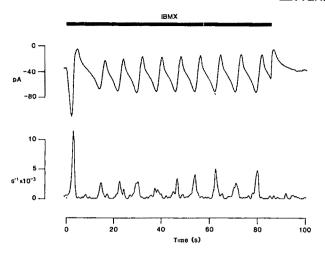

Fig. 1 Effect of exposure of the outer segment of an isolated rod loaded with aequorin to the phosphodiesterase inhibitor IBMX (0.5 mM). The upper panel shows the light-sensitive current recorded with a suction pipette. The lower panel shows the aequorin light output, expressed as rate of disintegration. The rate of disintegration was calculated as the ratio of the recorded count rate to the total counts in the cell, which were 5×10^3 ; the latter value was obtained by lysing the cell in 1 mM CaCl₂ at the end of the experiment and summing back the counts expended during the experiment. The period of oscillation was 8.3 s, and the peak aequorin light output occurred 0.63 s after the peak current. Methods. The traces were low-pass-filtered at 20 Hz; the aequorin light signal was in addition filtered digitally by convolving with a gaussian function of standard deviation 275 ms. This filtering operation does not cause a temporal shift. Composition of the normal Ringer's was (in mM): NaCl 110, KCl 2.5, MgCl₂ 1.6, CaCl₂ 1, glucose, 3, HEPES 10, neutralized to pH 7.6 with TMAOH (tetramethylammonium hydroxide). Composition of the solution filling the whole-cell pipette was (in mM): K-aspartate 110, EGTA 0.02, MgCl₂ 3, Na₂ATP 1, Na₂GTP 1, PIPES 10, neutralized to pH 7.2 with KOH. Aliquots of aequorin (0.1 µl at 20 mg ml⁻¹) were dialysed against the filling solution before use. The aequorin light was collected with a ×100 lens mounted on a Zeiss IM35 inverted microscope, and was focused onto the cathode of a photomultiplier tube (EMI 9789B) mounted in place of the binocular head. Single photons were counted by a Brookdeal quantum photometer. An aperture mounted at an intermediate image plane limited light collection to an area slightly greater than that of the outer segment.

Aequorin light came principally from the outer segment, as little

light was recorded with the aperture positioned over the inner segment¹³. The aperture was removed before lysis of the cell at

the end of the experiment.

The influx of Ca²⁺ into the cell can be measured directly by exposing the ROS to a solution in which all permeant ions have been replaced by Ca²⁺. Figure 3 shows an experiment of this kind. The influx of Ca²⁺ on exposure to isotonic Ca²⁺ was followed by a rise in the emission of light from the aequorin and a subsequent closure of light-sensitive channels. In contrast to the experiment of Fig. 2 (in the presence of a normal concentration of Na), there was little decline in the light emission after the closure of the channels; the observed slow decline in Fig. 3c is attributable largely to consumption of aequorin by the large increase in [Ca2+]i. On restoration of a normal concentration of Na, there was a rapid decline in [Ca2+], and a large light-insensitive pumping current. The rate of decline of free [Ca²⁺]; on restoration of Na was ~30 μM s⁻¹, compared with a rate of $< 0.6 \,\mu\text{M s}^{-1}$ in the absence of Na (see Fig. 3 legend). This experiment shows that the maximal activity of the Na/Ca exchange is at least 50 times greater than that of other Ca pumps in the outer segment membrane.

In the experiment shown in Fig. 3, the total charge flowing during the application of isotonic Ca^{2+} was 46 pC and the total charge transferred by the pump was 20.6 pC, consistent with a $3 \text{ Na}^+/1 \text{ Ca}^{2+}$ stoichiometry for the pump³. In this experiment

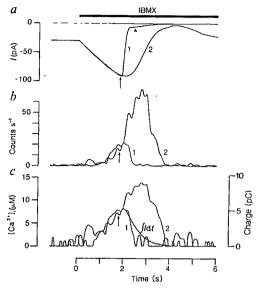

Fig. 2 Effect of a flash of light on [Ca²⁺]_i. a, Light-sensitive current obtained with a light flash (4.0×10⁴ Rh*) delivered at the arrow (trace 1), or in the dark (trace 2). The triangle marks the pumping current at the plateau of the light response. b, The aequorin light output. c, [Ca²⁺]; calculated from the rate of disintegration of aequorin by using a calibration curve supplied by Dr J. Blinks. Over the range $0.1 \,\mu\text{m} < [\text{Ca}^{2+}] < 30 \,\mu\text{m}$ and with free $[Mg^{2+}] = 1$ mM, the curve was well fitted by the function $[Ca^{2+}] =$ A(rate of disintegration)^y, where $A = 4.67 \times 10^{-5} \text{M}$ and y = 0.417. The integral of the pumping current (smooth trace, right-hand ordinate) is also shown in c. Traces are the mean of five presentations. The gaussian filter for the aequorum trace had a standard deviation of 65 ms. Total counts in the cell were 5.3×10^3 , and we assumed for the purpose of calculating [Ca2+]; that 26% of the aequorin was in the outer segment since this was the maximum fraction of the total counts which could be exhausted by a rapid elevation of [Ca2+]i.

the suction pipette collected 52% of the outer segment current, as judged by the ratio of bright flash responses recorded by the whole-cell pipette to those recorded by the suction pipette at the start of the experiment. From this collection ratio, and taking an outer segment volume of 2 pl, of which half is assumed to be occupied by the disks, we calculate that the total $[Ca^{2+}]_i$ increased by 458 μ M in the cytoplasmic space of the outer segment; the observed rise in $[Ca^{2+}]_i$ was less than this value by a factor of ~20, showing that about 95% of the Ca^{2+} entering the outer segment is bound and is not free to interact with aequorin. The binding mechanism must be rapid and reversible, as there was a good temporal correlation between the change in $[Ca^{2+}]_i$, as measured from the aequorin light output, and the integrals of both the Ca^{2+} influx and the pumping current.

Figure 4 shows the results of an experiment in which a large increase in light-sensitive current resulted from exposure to low external Ca^{2+} (ref. 4) in the absence of IBMX. In this experiment the increase in current did not cause an increase in [Ca]_i, but on return to Ringer's containing 1 mM Ca there was a large influx of calcium through light-sensitive channels and an increase in aequorin light emission. The subsequent decline in $[Ca^{2+}]_i$ correlates well with the time course of charge transfer by the pump (see Fig. 4c). The rate of decline was slower than in the experiments of Figs 2 and 3, perhaps because of the build-up of Na_i during the preceding large current flow. From the total charge transferred by the pump we calculate that 24% of the current flowing on return to normal Ringer's was carried by Ca^{2+} .

The results described here can be used to estimate the normal free $[Ca^{2+}]_i$ when the rod is bathed in Ringer's. In the presence of a bright light $[Ca^{2+}]_i$ is likely to be low, in view of our finding that the main route of entry is via the light-sensitive channel.

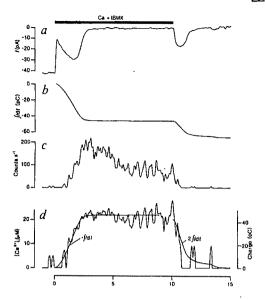

Fig. 3 a, Membrane current recorded during exposure to an isotonic CaCl₂ solution containing (in mM): CaCl₂ 77.6, HEPES 10 (pH 7.6), IBMX 0.5. The junction current has been subtracted⁴. The elevation in Ca²⁺ caused an initial rapid suppression of current, due to an external action⁴, followed by a rise due to the inhibition of phosphodiesterase by the IBMX. The subsequent decrease is due to closure of light-sensitive channels by the aequorin light emission; the light-sensitive current remained completely suppressed until after the end of the trace shown in a. b, Integral of the membrane current in a, beginning from the time of admission of isotonic Ca²⁺. Note that the integral of the current carried by Ca^{2+} is approximately double that of the pumping current. c, The aequorin light output. d, Calculated change in $[Ca^{2+}]_i$ (noisy trace, left-hand ordinate) based on the assumptions outlined in Fig. 2 legend. Based on these assumptions, no decline in $[Ca^{2+}]_i$ is observed during exposure to isotonic Ca^{2+} , and the rate of decline on restoration of Na is 30 µM s⁻¹. If instead we make the extreme assumption that all the aequorin is in the outer segment, then the rate of decline of $[Ca^{2+}]_i$ is $0.6\,\mu\text{M}\,\text{s}^{-1}$ during the exposure to isotonic Ca²⁺. Total counts in the cell were 4.6×10³. The smooth traces (right-hand ordinate) in d compare the time courses of the integrals of the light-sensitive and pumping currents with the time course of the change in [Ca²⁺],.

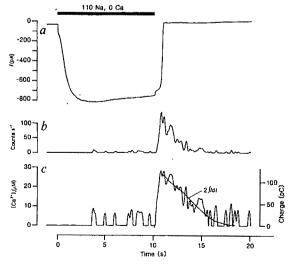

Fig. 4 Membrane current (a), aequorin light output (b) and $[Ca^{2+}]_i$ (c) during exposure to Ringer's containing 0 Ca and 2 mM BAPTA¹⁴. The smooth trace (right-hand ordinate) in c is the integral of the pumping current observed after all light-sensitive channels had been closed by the strong aequorin light emission. The absence of bumps at the beginning of the traces in b and c, which was not seen in other records, is not significant. Total counts in the cell, 1.86×10^3 . For other details, see Fig. 2 legend.

After a bright flash of light the pumping current at the plateau of the response declines with a time constant of ~ 0.5 s, and carries a total charge of ~0.5 pC, as measured with a suction pipette^{7,10}. If we assume a current collection efficiency of 50% and if the pump operates as a $3Na^{+}/1Ca^{2+}$ exchange, this charge transfer corresponds to a change in total [Ca²⁺]; of 10 µM when distributed over an effective outer segment volume of 1 pl. If 95% of this Ca²⁺ is bound, the free [Ca²⁺]_i in the dark will be 0.5 µM, which is slightly below our present detection limit of 0.6 µM. As we find that the time course of decline of free [Ca²⁺ correlates well with the time course of the integral of the pumping current, we expect that the effect of a bright flash will be to reduce [Ca²⁺], from its dark level of ~0.5 μM to a much lower level with a time constant of ~ 0.5 s.

This work was supported by the MRC and by an EMBO fellowship (to L.C.). B.J.N. is a Lister Institute Research Fellow. We thank Drs J. R. Blinks and P. H. Cobbold for supplies of aequorin and for advice, and Professor A. L. Hodgkin, Dr T. D. Lamb and Mr L. Lagnado for helpful discussions.

Mediation of thalamic sensory input by both NMDA receptors and non-NMDA receptors

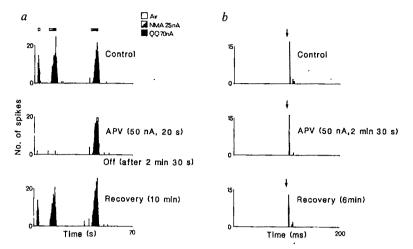

T. E. Salt

Department of Physiology, University College, Cardiff, PO Box 78, Cardiff CF1 1XL, UK

Excitatory amino acids such as L-glutamate and L-aspartate are well established as neurotransmitter candidates in the mammalian central nervous system¹, and three types of receptor for these substances have been proposed, characterized by the agonists N-methyl-D-aspartate (NMDA), kainate and quisqualate¹. All these receptors have been suggested to have synaptic roles in excitatory transmission in the brain¹⁻⁷. Here I demonstrate that NMDA receptors play a crucial role in the observed response of ventrobasal thalamus (VB) neurones to natural stimulation of somatosensory afferents, but do not appear to be responsible for the short-latency excitation seen on electrical stimulation of the afferents, which is apparently mediated by excitatory amino-acid receptors of the non-NMDA type. This result indicates an involvement of both NMDA and non-NMDA receptors in the responses of VB neurones to stimulation of somatosensory afferents, depending on the mode of stimulation of the pathway.

Recordings, using extracellular iontophoretic electrodes, were made from single neurones in the ventrobasal thalamus of rats anaesthetized with urethane (1.2 g per kg intraperitoneal). Responses of VB neurones to physiological stimulation of hair or vibrissa follicle afferents (using an air jet) and iontophoretic application of N-methylaspartate (NMA) and either kainate (14 neurones) or quisqualate (14 neurones), were challenged

Fig. 1 Peristimulus time histograms of action potentials recorded from a single VB neurone with one barrel of a five-barrelled iontophoretic electrode. Action potentials were discriminated on the basis of amplitude and waveform. The vertical axis of each histogram is the number of action potential spikes counted into epochs of either 250 ms (a) or 1 ms (b). Each drug barrel of the electrode contained one of the following: N-methylaspartate (NMA, 0.2 M, pH 8.0), quisqualate (QQ, 25 mM in 75 mM NaCl, pH 8.0), kainate (KA, 0.1 M, pH 8.0), APV (50 mM in 150 mM NaCl, pH 8.0), kynurenate (KYN, 50 mM, pH 8.0), acetylcholine (ACh, 0.5 M, pH 3.5), carbamylcholine (CCh, 0.2 M, pH 4.0) or 1 M NaCl. Automatic current balancing was used in this experiment, but qualitatively identical results were found in experiments where balancing was not performed. In three experiments a sevenbarrelled electrode was used. a, Top record shows the control responses (averaged over two trials) of a neurone to an air jet, directed so as to deflect the hairs within its receptive field, and to iontophoretic application of NMA

and QQ. The three stimuli were applied at the time and for the durations indicated by the bars above the record. The middle record shows the responses of the same neurone to the same three stimuli, but during the concurrent ejection of APV. APV antagonized the responses to the air jet stimulus and NMA, but had little effect on the response to QQ. The bottom record shows the same sequence, but 10 min after termination of the APV ejection when responses to the air jet and NMA had recovered to their control levels. b, Response of the same neurone as in a to electrical stimulation (0.1-ms pulse, 10 V, 0.5-Hz repetition rate) of the afferent pathway delivered via needle electrodes within the peripheral receptive field. In all experiments the stimulus intensity was adjusted to the minimum necessary to evoke a short-latency response. The time of stimulation is indicated by an arrow above each histogram. The records are averaged over 20 trials. The middle record shows the response of the neurone to the stimulus during the ejection of APV. The antagonist had little effect on the electrically evoked response, even though the APV ejection was for a longer duration than that necessary to antagonize responses to the air jet and NMA.

with concurrent application (0-50 nA) of the selective NMDA antagonist D-2-amino-5-phosphonovalerate $(APV)^1$. This antagonist was found to antagonize the responses to NMA but not responses to kainate or quisqualate, and had little effect on the spontaneous activity of VB neurones. It was also possible to antagonize the responses of the VB neurones to the physiological stimulus by 42-100% (mean = 80%), using the same APV ejection currents, in 26 of the 28 neurones studied in this way (Fig. 1a). The response of 11 of these neurones to single-pulse electrical stimulation of the afferent pathway was then studied. The

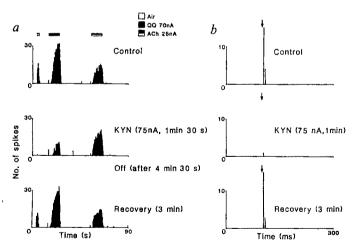

Fig. 2 a, Similar records to those in Fig. 1, but from another neurone which responded to the air jet stimulus and to iontophoretic ejection of QQ and ACh applied as indicated by the bars above the records. Below the control record is shown the same sequence during the ejection of kynurenate (KYN). A complete antagonism of the air jet response was evident, and the responses to QQ were also greatly reduced. No reduction in the response to ACh was seen. The bottom record shows recovery from the effects of kynurenate 3 min after the end of the antagonist ejection. b, Responses of the same neurone to single-pulse electrical stimulation in its peripheral receptive field at the time indicated by the arrows (15 trials). Middle record shows the response of the neurone during the ejection of kynurenate. The antagonist greatly reduced the response to the stimulus.

short-latency (4-10 ms) response evoked by such a stimulus was challenged with the same iontophoretic current of APV that had previously been found to be effective against NMA and the physiologically evoked response, and in all of these cases the antagonist was found to be ineffective against the electrically evoked response (Fig. 1b). In contrast, the broad-spectrum excitatory amino-acid antagonist kynurenate^{4,8} (10-150 nA), which antagonized the responses of VB neurones to quisqualate in addition to the responses to NMA and the physiological stimulus, blocked the responses to electrical stimulation by 54-100% (mean = 86%) in 11 neurones (Fig. 2). Responses to the cholinergic agonists acetylcholine and carbamylcholine remained largely unaffected by kynurenate, although in some cases a small excitatory effect of the antagonist became evident.

These results suggest that an excitatory amino acid functions as the transmitter mediating the responses of VB neurones to stimulation of second-order sensory afferents. This mechanism is consistent with those suggested previously^{9,10}, and with data on the retino-geniculate projection^{11,12}. In addition, it seems likely that the excitation observed in response to stimulation of the afferent pathway is composed of at least two separate components. The first of these components, which can be selectively evoked at short latency by single-pulse electrical stimulation in the peripheral receptive field, is apparently mediated by excitatory amino-acid receptors of the non-NMDA type, as it is antagonized by kynurenate but not by APV. It is unlikely that this response is resistant to APV because the response has a high safety factor, as threshold stimulus intensities were used and the response could be antagonized by kynurenate, which might be expected to be ineffective if the response had a high safety factor. The finding that the response of VB neurones to physiological stimulation of the sensory afferents is greatly reduced by the selective NMDA antagonist APV implies an additional response component, which is mediated by NMDA receptors and which is recruited during physiological stimulation. It is tempting to speculate that it is the pattern of afferent activity which governs the recruitment of the APV-sensitive response, as the response of the VB neurones to the air jet is a train of action potentials (typically of frequency ~20 Hz) lasting for the duration of the stimulus (0.5-2 s), while the response to the single-pulse electrical stimulus is one or two action potentials. To test this possibility further, electrical stimulation was performed in 20-Hz trains on 10 neurones in which APV was found to antagonize the physiologically evoked response. For nine of these neurones, APV was found to antagonize the response to the stimulus train. In particular, the later components of the response appeared more susceptible to APV (Fig. 3). Note that the APV-sensitive component of this response does not appear to be larger than the APV-insensitive component; this suggests that the APV-insensitive component becomes less effective during the stimulus train, possibly because of activation of inhibitory processes in the thalamus¹³. Clearly, experiments using intracellular recording would provide further information on this matter.

It is conceivable that, under physiological conditions, the NMDA receptor component potentiates an already present, but possibly sub-threshold, excitatory input mediated by non-NMDA excitatory amino-acid receptors (presumably of the kainate or quisqualate type). This hypothesis is attractive in view of recent work which shows that responses of neurones to NMDA are subject to voltage-dependent blockade by Mg2+ ions in the physiological concentration range for Mg²⁺ (refs 6, 14, 15), and it is noteworthy that a postsynaptic potential involving a short-latency non-NMDA component and an NMDA component of longer latency have been found in the spinal cord of Xenopus¹⁶. The recruitment of NMDA receptors could be a purely synaptic phenomenon similar to the APV-sensitive longterm potentiation observed in the hippocampus⁷, and might involve one type of excitatory amino acid being released onto both NMDA and non-NMDA receptors. Alternatively, the two types of response could be mediated by two afferent pathways to the thalamus which terminate on the same neurone. Evidence for such multiple pathways already exists 17,18

The NMDA receptor-mediated response of VB neurones to physiological stimulation of afferents provides a possible site of action for the dissociative anaesthetic ketamine, which has been shown to possess NMDA antagonist properties^{6,19}. This contrasts with previous findings in the dorsal horns of the spinal cord²⁰ and medulla³, where NMDA antagonists were found to be ineffective in blocking responses to air jet deflection of hairs and vibrissae. As there are no major procedural differences between the present experiments and those performed on the medullary dorsal horn³, it seems likely that the observed difference reflects a regional difference between the dorsal horn and thalamus. Thus, it is possible that the thalamus is a major site for the anaesthetic action of ketamine.

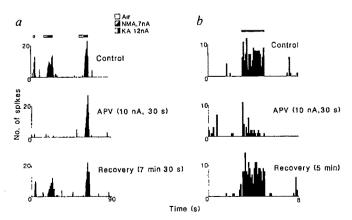

Fig. 3 a, Similar records to those in Fig. 1 (500 ms epochs), but from a neurone responding to air jet stimulation and iontophoretically applied NMA and kainate (KA). APV selectively and reversibly antagonized the responses to the air jet and NMA. b, Records from the same neurone as in a, showing the responses to a train of electrical stimuli (20 Hz, 0.1-ms pulse, 2 s duration, 100 ms epochs, 5 trials). The time of stimulation is indicated by the vertical lines above the top record. The middle record shows the response of the neurone during the ejection of APV, and the bottom record shows the recovery after termination of the APV ejection.

I thank Ms V. Crimmins for technical assistance. This work was supported by the MRC (UK).

Frequency-dependent involvement of NMDA receptors in the hippocampus: a novel synaptic mechanism

Caroline E. Herron, Robin A. J. Lester, Elizabeth J. Coan & Graham L. Collingridge

Department of Pharmacology, University of Bristol, Medical School, University Walk, Bristol BS8 1TD, UK

Acidic amino acids, such as L-glutamate, are believed to be excitatory neurotransmitters in the mammalian brain 1,2 and exert effects on several different receptors named after the selective agonists kainate, quisqualate and N-methyl-D-aspartate (NMDA)1. The first two receptors, collectively termed non-NMDA receptors, have been implicated in the mediation of synaptic transmission in many excitatory pathways in the central nervous system (CNS), whereas NMDA receptors, with few exceptions, do not appear to be involved2; this is typified in the hippocampus where there is a high density of NMDA receptors3 yet selective NMDA receptor antagonists, such as D-2-amino-5-phosphonovalerate (APV), do not affect synaptic potentials⁴⁻¹¹. NMDA receptors have, however, been shown to be involved in long-term potentiation (LTP) in the hippocampus⁶⁻¹¹, a form of synaptic plasticity¹² which may be involved in learning and memory¹¹. NMDA receptors have also been found to contribute to epileptiform activity in this region 13,14. We now describe how NMDA receptors can participate during high-frequency synaptic transmission in the hippocampus, their involvement during low-frequency transmission being greatly suppressed by Mg2+. A frequency-dependent alleviation of this blockade provides a novel synaptic mechanism whereby a single neurotransmitter can transmit very different information depending on the temporal nature of the input. This mechanism could account for the involvement of NMDA receptors in the initiation of LTP and their contribution, in part, to epileptic activity.

Experiments were performed on transverse hippocampal slices prepared from adult female rats as described previously¹⁵. The standard perfusion medium comprised (in mM): NaCl 124, NaHCO₃ 26, NaH₂PO₄ 1.2, KCl 3 or 5, MgSO₄ 1 or 2, CaCl₂ 2, D-glucose 10. Extracellular and intracellular recordings were obtained from the CA1 cell body region using electrodes containing NaCl (1-4 M) and CH₃COOK (3 M), respectively. The Schaffer collateral-commissural pathway was stimulated with single shocks delivered at 10-30-s intervals to elicit 'low-

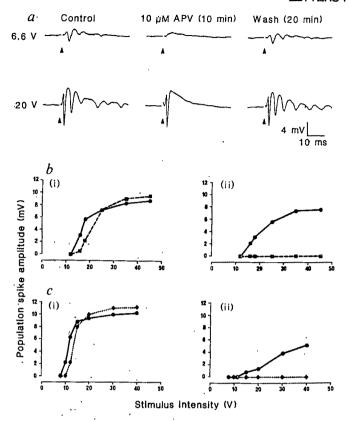

Fig. 1 Effects of NMDA antagonists on field potentials recorded extracellularly from the CA1 cell body region in response to low-frequency stimulation of the Schaffer collateral-commissural pathway. a, Effect of 10 μM APV on responses at two stimulus intensities (6.6 V and 20 V). b, Amplitude of the primary (i) and secondary (ii) population spikes as a function of stimulus intensity in control medium (continuous line) and in the presence of 20 μM APV (broken line) in another hippocampal slice. c, Data presented in the same manner as b for a different slice, showing the effects of 100 μM Mg²⁺.

frequency' synaptic responses and for periods of 200 ms at 10-ms intervals to evoke 'high-frequency' responses. The selective NMDA antagonist APV was administered via the perfusion medium (flow rate $1-2 \text{ ml min}^{-1}$). In the absence of APV, high-frequency stimulation often produced LTP of the excitatory postsynaptic potential (e.p.s.p), therefore periods of high-frequency stimulation were delivered first in the presence and subsequently following washout of APV. The data were tested for significance (P < 0.05) using paired Student's t-tests.

Field potentials were recorded from the CA1 cell body region in response to low-frequency stimulation of the Schaffer collateral-commissural pathway with no $\mathrm{Mg^{2+}}$ in the bathing medium ¹⁶. At low stimulus intensities the synaptic response was greatly suppressed (Fig. 1a) or abolished by 10 or 20 μ M APV. In contrast, at higher stimulus intensities, the secondary population spikes were abolished while the primary population spike was little affected by APV (Fig. 1a, b), presumably because non-NMDA excitatory amino-acid receptors could sustain this component of the response⁶. These effects were fully reversible and seen in all 10 hippocampal slices examined. An identical pattern of antagonism was also observed with $\mathrm{Mg^{2+}}$ (100 μ M) in all four slices tested (Fig. 1c).

These results demonstrate for the first time that NMDA receptors mediate a synaptic response in hippocampal neurones that has as low a threshold as that of non-NMDA receptors, provided Mg²⁺ is absent from the extracellular medium; this could be accounted for by the neurotransmitter having a high affinity for NMDA receptors, which would only be seen functionally when the Mg²⁺ block of NMDA channels was removed. The con-

centrations of Mg^{2+} (dose-dependent over the range $20-500~\mu M$) that affect this component are the same as those that directly block postsynaptic responses to $NMDA^1$ and are much lower than those expected to affect significantly transmitter release¹⁷ or membrane stabilization¹⁸; they are also much lower than the generally accepted levels of Mg^{2+} in extracellular fluid. It is likely, therefore, that a major action of Mg^{2+} in the hippocampus is to exert a powerful controlling influence on synaptic transmission by a direct interaction with the NMDA receptor system.

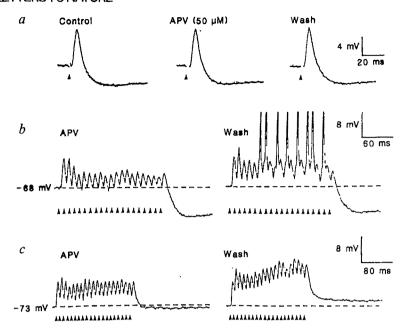

A second series of experiments was performed to determine the extent of the involvement of the NMDA receptor system in synaptic transmission in the hippocampus in the presence of physiological concentrations of Mg²⁺ (1-2 mM). Passive membrane properties, determined for 27 CA1 neurones (resting membrane potential -69±1 mV; input resistance, calculated near the resting membrane potential, $27 \pm 1 \text{ M}\Omega$), were not altered significantly by APV (20 or 50 µM). Stimulation of the Schaffer collateral-commissural pathway at low frequencies evoked a fast e.p.s.p. which was unaffected by APV (Fig. 2a). Measurements (mean ± s.e.m.) of peak amplitude and duration at 50% of peak amplitude in control solutions $(8.3 \pm 0.6 \text{ mV}; 9.6 \pm 0.8 \text{ ms})$ and in the presence of APV $(8.4\pm0.6 \text{ mV}; 9.3\pm0.6 \text{ ms})$ were not significantly different (n=32). The inhibitory postsynaptic potential (i.p.s.p.) which followed the fast e.p.s.p. was generally unaffected by APV (Fig. 2a).

In contrast to the lack of effect on low-frequency synaptic responses, APV had a marked effect on the synaptic response generated by high-frequency stimulation. During highfrequency stimulation, fast e.p.s.ps were associated with a slow depolarizing potential. APV (20 or 50 µM) had no effect on fast e.p.s.ps evoked during high-frequency stimulation (Fig. 2c); it did, however, reduce the size of the associated slow depolarization, measured from the pre-stimulus membrane potential to the base of the fast e.p.s.ps, in 17 of 22 neurones examined (Fig. 2b, c). The mean (\pm s.e.m.) amplitude of the depolarization. measured at 140-150 ms into the high-frequency train, for these 17 cells in the presence and after washout of APV, was $5.3 \pm$ 0.9 mV and $8.3 \pm 1.0 \text{ mV}$, respectively. The size of the NMDA receptor-mediated potential calculated individually for each cell varied between 0.9 and 5.1 mV (mean \pm s.e.m., $3.0 \pm 0.2 \text{ mV}$). This NMDA receptor-mediated e.p.s.p. became apparent in some cells as early as the second fast e.p.s.p. in the high-frequency train (Fig. 2b, c).

The lack of effect of APV on low-frequency synaptic transmission in the Schaffer collateral-commissural pathway is in agreement with previous reports using extracellular recording⁵⁻⁹. but contrasts with a recent intracellular study which reported that APV depressed the fast e.p.s.p. 19. The latter effect can be attributed to the use of high concentrations of the racemic mixture of APV, which has previously been shown to depress synaptic transmission in this pathway by an action unrelated to NMDA-receptor antagonism⁷. As low-frequency synaptic responses in this pathway can be reduced by broad-spectrum excitatory amino-acid antagonists, such as y-D-glutamylglycine⁶, it is believed that receptors of the kainate or quisqualate (that is, non-NMDA) type are responsible for fast e.p.s.ps. The present study has shown that an NMDA receptor-mediated e.p.s.p. can be recorded in this pathway during high-frequency stimulation, but the slow nature of this synaptic response as well as its activation characteristics clearly distinguished it from the fast e.p.s.ps. The observation that the NMDA receptormediated synaptic potential could often be detected as early as the second fast e.p.s.p. during high-frequency stimulation (see Fig. 2b, c) demonstrates that as few as two appropriately timed synaptic inputs may activate the NMDA receptor system in the hippocampus.

The finding that in the absence of Mg²⁺, low-frequency stimulation activates a low-threshold NMDA receptor-mediated synaptic response, implies that NMDA receptors are normally acted on by the neurotransmitter released by low-frequency

Fig. 2 Effect of 50 µM APV on synaptic responses recorded intracellularly in CA1 neurones in response to stimulation of the Schaffer collateral-commissural pathway. a, Averages of five successive records of synaptic potentials evoked at 30-s intervals before (control), during and after washout of APV. b, Single records of responses of the same cell to high-frequency stimulation (20 shocks at 10-ms intervals) in the presence and following washout of APV. The e.p.s.p.s shown in a (centre and right-hand records) were obtained immediately before the two respective periods of high-frequency stimulation. c, Single records of responses to high-frequency stimulation in another cell. The times of stimulation are indicated by arrowheads and stimulus artefacts have been blanked out for clarity. Stimulus intensity and membrane potentials were constant throughout. Action potentials in b are truncated.

stimulation. It is not necessary, therefore, to postulate that high-frequency stimulation is required either to release an additional agonist for NMDA receptors or to increase neurotransmitter release sufficient to activate the NMDA receptors due to their localization or activation characteristics. A simpler hypothesis^{20,21} which agrees fully with the present observations is that a single neurotransmitter acts simultaneously on both non-NMDA and NMDA receptors but that the latter are prevented from participating appreciably in low-frequency synaptic transmission by Mg²⁺. During high-frequency stimulation this Mg²⁺ blockade of the NMDA receptor system may be temporarily alleviated, allowing Ca²⁺ and Na⁺ to enter via the NMDA channels^{6,22-25}, and lead to the induction of LTP²⁶. This inward movement of cations through the NMDA channels could account for the slow e.p.s.p. recorded in the present study. It is likely that depolarization of the synaptic membrane, caused in part by temporal summation of fast e.p.s.ps, could be the mechanism by which the blockade is reduced. In this respect, it has been shown using cultured neurones that Mg2+ directly blocks NMDA-gated channels and that this block is reduced by membrane depolarization²⁷. In addition, it has been reported recently that pairing single afferent synaptic inputs with postsynaptic depolarization can activate the NMDA receptor system and elicit LTP28

It has been shown that NMDA receptors are involved in epilepsy²⁹. In the presence of convulsant drugs, an NMDA receptor-mediated potential has been recorded extracellularly in the hippocampus during brief periods of high-frequency stimulation⁸, and a small NMDA receptor-mediated component of the fast e.p.s.p. recorded extracellularly²¹ or intracellularly^{13,14} has been detected during low-frequency stimulation. The latter effect has been explained on the basis of removal of the Mg²⁺ block of NMDA channels, the necessary depolarization being provided by the fast e.p.s.ps prolonged by the action of the convulsant drug¹⁴. Such a mechanism could operate at the centre of an epileptic focus where synaptic inhibition may be impaired. The present results suggest a second way in which the NMDA receptor system may contribute to epileptic activity—by amplifying the synaptic output in response to a high-frequency input in the presence of fully functional synaptic inhibition (that is, absence of convulsant drugs). The synchronized, high-frequency discharge of neurones in epileptic tissue would provide ideal conditions for the activation of the NMDA receptor system such that this system could contribute to the propagation of epileptic activity through normal brain tissue.

It is now widely believed that NMDA receptors are important for synaptic plasticity in the hippocampus, but their function elsewhere in the brain is generally less clear. Although it is probable that NMDA receptors will be found to be involved in plastic processes in other regions of the CNS (for example, the cerebral cortex), their involvement in the discharge pattern of spinal interneurones¹, transmission of afferent sensory input³⁰ and generation of locomotor patterns³¹ is also indicated. As ions are a potent NMDA antagonist in all regions of the brain so far examined, it is likely that a synaptic mechanism similar to that proposed here for hippocampal neuronal transmission will apply throughout the CNS.

Since submission of this manuscript, it has been reported³² that postsynaptic hyperpolarization during conditioning reversibly prevents the initiation of LTP. These authors proposed that this was caused by the hyperpolarization preventing activation of voltage-gated calcium channels. On the basis of our present findings, we suggest a refinement of this hypothesis: that hyperpolarization prevented LTP by opposing the depolarization necessary to alleviate the Mg²⁺ block of NMDA channels.

The inducible cytotoxic T-lymphocyte-associated gene transcript CTLA-1 sequence and gene localization to mouse chromosome 14

Jean-François Brunet, Magali Dosseto, François Denizot, Marie-Geneviève Mattei*, William R. Clark‡, Tariq M. Haqqi, Pierre Ferrier, Markus Nabholzt, Anne-Marie Schmitt-Verhulst, Marie-Françoise Luciani & Pierre Golstein

Centre d'Immunologie INSERM-CNRS de Marseille-Luminy, Case 906, 13288 Marseille Cédex 9, France INSERM U.242, CHU Timone, 13385 Marseille Cedex 5, France. † Swiss Institute for Experimental Cancer Research, Epalinges CH-1066, Switzerland.

Classical phenomenological approaches to the study of the mechanism of T-cell-mediated cytotoxicity 1-3 have now given way to a search for molecules involved in this function; this is attempted either by subcellular and biochemical fractionation of material from cytotoxic cells^{4,5}, or through the characterization of molecules recognized by cytotoxicity-inhibiting monoclonal antibodies (see ref. 6 for a review). Molecules having a role in cytotoxicity may also be identified by detecting the corresponding messenger RNA transcripts. Such an approach may include, as a first step, the search for transcripts as specific as possible to cytotoxic T cells; only secondarily can their actual relevance to cytotoxicity be investigated. We report here the preparation and systematic screening of a differential complementary DNA bank, in which we detected three distinct messenger RNA transcripts (CTLA-1, CTLA-2 and CTLA-3) present in various cytotoxic T cells but not (or less so) in a range of non-cytotoxic lymphoid cells. We describe the co-inducibility of these transcripts and of cytoxicity in thymocytes and hybridoma cells, the sequence of CTLA-1 cDNA, its protein homology with serine esterases and the localization of the corresponding gene to mouse chromo-

A library was derived from cDNA obtained by subtractive hybridization⁷⁻¹¹ between cDNA from the B10.BR anti-H-2K^b cytotoxic T-cell clone KB5C20 (ref. 12; hereafter designated T_c) and mRNA from the B-lymphoma M12.4.1 (ref. 13; hereafter designated B). The 8,300 recombinant cDNA clones obtained were subjected to three successive rounds of screening with radioactive cDNA probes prepared from a range of cytotoxic and non-cytotoxic cells. In the first round of screening, 230 of the 8,300 cDNA clones gave a signal with a T_c probe but not with a B probe. These 230 T_c B clones were subjected to a second round of screening using radioactive cDNA probes from T_c, B, T_h (T-helper cells, that is, the T-lymphoma EL4), thymocytes or brain. The results are summarized in Table 1. The 230 clones fell into a number of specificity patterns, with only 73 of them remaining 'T_c-specific'.

These 73 clones were hybridized with cDNA probes made from (1) RDM4, another non-cytotoxic T-cell lymphoma, detecting no clones, (2) EL4 cells, now activated with phorbol myristate acetate, which detected five 'activation-associated'

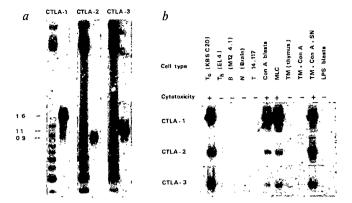

Fig. 1 Size and specificity patterns of CTLA-1, CTLA-2 and CTLA-3 RNA transcripts. Northern blots of RNA from the T_c clone KB5C20 (a) and from 11 cytotoxic and non-cytotoxic cell types (b) were probed with the inserts of plasmid M41D12, M41G12 or M11E6, representive of CTLA-1, CTLA-2 and CTLA-3, respectively. Cell types were as in Table 1, plus: T14.117, a hybridoma between a T-helper cell clone and the BW5147 thymoma²⁴; MLC cells, A/J spleen cells stimulated for 5 days in vitro with C57BL/6 irradiated spleen cells; TM+Con A, C57BL/6 thymocytes incubated for 24 h in the presence of 5 µg ml⁻¹ of Con A; TM+Con A+SN, TM+Con A further incubated for 5 days in the presence of IL-2-containing supernatant from PMA-stimulated EL4 C116 cells. At the time of RNA extraction, the cells were tested for cytotoxicity and classified as cytotoxic (+) or noncytotoxic (-) according to the criteria given in Table 1. In a, an end-labelled 123-bp ladder (BRL) was used as a size marker. In b, a control actin probe gave a distinct band in all lanes (not shown). Methods. Total RNA (10 µg per lane) was run for 3-6 h at 2.5 V on a 1.1% formaldehyde-agarose gel, in MOPS buffer, then transferred to nitrocellulose filters. Inserts, obtained either from CsCl-purified plasmids or from minipreparations of plasmids, digested with PstI and separated on 2% LMP (low melting point) agarose (BRL) gels, were labelled by random priming²⁵ and used as probes on Northern blots. Blots were prehybridized in 5×SSC, 50% formamide, 5 × Denhardt's, 5 mM EDTA, 0.1% SDS, 50 mM phosphate buffer pH7 and 7% dextran sulphate, at 42 °C for 4-12 h. Hybridization was in the same buffer, to which the probe was added at 10⁶ d.p.m. ml⁻¹, for 12 h at 42 °C. Washes were for 10 min in 2×SSC, 0.1% SDS and for 30 min in 0.2×SSC, 0.1% SDS at 65 °C.

clones, (3) lipopolysaccharide (LPS)-stimulated blasts, detecting two clones, and (4) a mixture of 2-day-old and 3-day-old cytotoxic concanavalin A (Con A) blasts, which failed to detect nine cDNA clones that previously were found to be positive with a T_c probe. The latter clones might, therefore, be associated with long-term in vitro growth of T cells rather than with cytotoxicity. Also, 8 of the 73 T_c⁺ clones proved to be negative with a subtracted (T_c-B) cDNA probe, which was taken as an indication of non-T_c-specificity. Altogether, after this third round of screening, only 50 T_c-specific cDNA clones were retained for further study.

In order to identify clones corresponding to the same genes, inserts (of 200 to 1,400 base pairs, bp) from individual clones were purified and hybridized to all of the 50 clones. This approach identified five groups of cDNA clones. Of these, on the basis of transcript size as determined by Northern blotting (Fig. 1a), three groups were clearly distinct. These were designated CTLA-1, CTLA-2 and CTLA-3, and included at least 3, 3 and 39 cDNA clones, respectively. Transcripts were detected as single bands of 1.6 kilobases (kb) for CTLA-1, 0.9 kb for CTLA-2 and 1.1 kb for CTLA-3 (Fig. 1a). CTLA-1, CTLA-2 and CTLA-3 transcripts were present in all the cytotoxic cell populations tested (T-cell clones, mixed leukocyte culture cells, Con A blasts and thymocytes activated with Con A plus interleukin-2 (IL-2)-containing EL4 supernatant). The CTLA-1 transcript was not detected in brain cells or in a range of non-

Two hundred and thirty $T_c^+B^-$ clones were transferred to filters and probed by hybridization with radioactive cDNA derived from, respectively, T_c (cytotoxic T-cell clone KB5C20), T_h (EL4 thymoma), TM (C57BL/6 thymocytes), B (M12.4.1 B-lymphoma cells) and N (C57BL/6 brain cells). + Indcates that a given collection hybridized detectably with the cDNA probe used, – that it did not. A few cDNA clones were lost during transfers and are not included. Forty clones did not give any positive signal and were considered false positives from the initial screening. Reciprocally, 17 clones gave a signal with the B probe and were considered false negatives from the initial screening. Only the 73 T_c -specific clones were subjected to further screening, although some of the rejected clones may be of interest in their own right.

Methods. Unselected total RNA was extracted by the LiCl method²⁰ from clone KB5C20 and the B lymphoma M12.4.1. Poly(A)+ RNA was selected by two passages over oligo(dT)-cellulose. KB5C20 single-stranded (SS) cDNA was synthesized from 5 µg of poly(A)* RNA in 100 mM Tris-HCl pH 8.3, 100 mM KCl, 10 mM MgCl₂, 10 mM dithiothreitol, 1 mM each of dA, dT and dG, 0.1 mM dC, 50 μ Cl ³²P-dCTP, oligo(dT₁₀) at 2 U ml⁻¹ and 6 U of reverse transcriptase (super RT, Stehelin) for 1 h at 42 °C. Single-stranded cDNA (1.3 μ g) was hybridized to M12.4.1 poly(A) * RNA (2 μ g μ l * 1) in 10 μ l of 0.4 M phosphate buffer pH 7.5, 1 mM EDTA, 0.1% SDS, overlaid with paraffin oil, for 20 h at 68 °C. After dilution in preheated 0.12 M phosphate buffer, the reaction was fractionated on a 1-ml hydroxyapatite column at 65 °C. The single-stranded fraction was precipitated in 50 mM EDTA pH 8, 0.1% cetylpyridinium bromide as described else-, except that an additional ethanol precipitation step was performed. The subtractive hybridization was repeated once, followed by an homologous hybridization with KB5C20 poly (A)+ RNA. The double-stranded fraction was precipitated as before, resuspended in H2O and the RNA hydrolysed in 0.1 N NaOH. Thirty nanograms of single-stranded cDNA was recovered at this stage, that is, 6.4% of initial cDNA (notwithstanding nonspecific losses). Second-strand synthesis and elongation, S₁-nuclease digestion and dC tailing were performed as described elsewhere²². Fourteen nanograms of tailed cDNA were annealed to dGMP-tailed Pst1-cut pBR322 plasmid (NEN) and used to transform Escherichia coli strain C600 according to the procedure of Hanahan²³. A total of 8,300 tetracyclineresistant, β -lactamase-negative (selected using Ampscreen, BRL) bacterial colonies containing recombinant plasmids were individually picked and grown into microtitre plate wells, replicated onto nitrocellulose filters and hybridized to 32 P-labelled cDNA synthesized as described above (however, with 50 μ M each of cold dG and dT, and 100 μ Ci each of 32 P-dT and 32 P-dG) from poly(A)⁺ RNA extracted from the following cells: Te (KB5C20) and B (M12.4.1) for a first round of differential screening, and the same plus T_h (thymoma EL4 C116), TM (C57BL/6 thymus) and N (C57BL/6 adult brain) for a second round on the $T_c^+B^$ clones selected in the first round. The results of this second round are presented above. Hybridizations were in 50% (v/v) formamide, 5×SSC, 5×Denhardt's, single-stranded DNA, for 48 h at 42 °C; washes were twice for 30 min each in 2×SSC, 0.1% SDS and twice for 30 min each in 0.2×SSC, 0.1% SDS at 65 °C. All the cells mentioned in this paper were tested, at the time of nucleic acid extraction, for their cytotoxic activity (or lack of it) in a conventional 4-h 51Cr-release test in the presence of the lectin Con A on both EL4 and RDM4 target cells. Cells were considered cytotoxic if they gave more than 20% specific Cr-release at a 20:1 effector to target cell ratio. In the absence of Con A, Tc specifically lysed EL4 but not RDM4 target cells, and induced PC60 cells lysed YAC target cells. To avoid contamination with feeder cell material, before extraction of RNA, Tc were grown for three passages without allogeneic feeder cells in the presence of EL4 C116 supernatant.

cytotoxic lymphoid cells (B-lymphoma cells, LPS blast cells, EL4 cells, normal thymocytes, Con-A-pulsed thymocytes, and hybridoma cells between a helper cell clone and BW5147 thymoma cells), even on overexposed films (Fig. 1b). The CTLA-2 transcript was detected in none of the non-cytotoxic cells at the exposure shown in Fig. 1b; with a longer exposure, faint bands appeared for all cells but the EL4 and B-lymphoma cells. The CTLA-3 transcript was detected in thymocytes and LPS blasts at the exposure shown in Fig. 1b, albeit less markedly than in the cytotoxic cells. These deviations from a strict T_c specificity had not been detected with the less sensitive methods used in the initial rounds of screening.

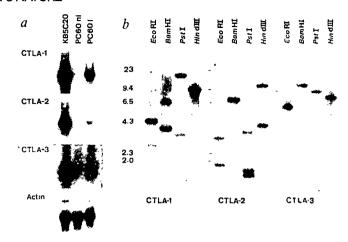

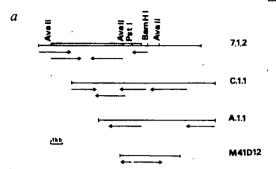

Fig. 2 Inducible transcription and Southern patterns of CTLA genes. a, Northern blots of RNA from KB5C20 (positive control) and non-induced (ni) or induced (i) PC60 hybridoma cells were probed with plasmid inserts representative of CTLA-1, CTLA-2 and CTLA-3, respectively, and with a control actin probe (given by M. Buckingham via C. Goridis); induction of PC60 cells also led to the appearance of cytotoxicity (not shown). Exposure times were different for each probe. b, Southern blots of DNA from mouse liver cells, cut with the indicated restriction enzymes, were probed with the same plasmid inserts; the numbers on the left are HindIII-derived size markers (in kb). Identical patterns were obtained with BALB/c liver, B10.BR liver or KB5C20 DNA (not shown)

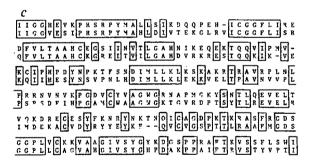

Methods. Northern blots were performed and probed as described in Fig. 1 legend. PC60 hybridoma cells were induced by adding IL-1- and IL-2-containing supernatant to PC60 cells as described previously²⁶ (we used the PC60-21-14-4 subclone of PC60). For Southern blots, DNA was prepared and purified by centrifugation to equilibrium in CsCl essentially as described elsewhere27, except that a higher concentration of Tris and EDTA was used in homogenizing buffer. Genomic DNA (10 µg) was digested to completion with EcoRI, BamHI, PstI or HindIII according to the conditions specified by the manufacturer (Boehringer Mannheim), electrophoresed for 16 h in 0.8% agarose gel in TAE (tris-acctate-EDTA) buffer and transferred to Gene Screen Plus (Du Pont). Blots were prehybridized for 6 h at 65 °C in 6 × SSC, 5 × Denhardt's. 1% SDS, 10 mM EDTA and 150 µg ml⁻¹ denatured salmon sperm DNA. Probes were labelled²⁵ to high specific activity (1.6 × 10⁹ c.p.m. μg⁻¹). Hybridization medium was as above plus 10% dextran sulphate and denatured probe (8×106 c.p.m. ml-1). Blots were hybridized overnight, then washed down to $0.2 \times SSC$ at 65 °C for 100 min, dried and exposed to film overnight.

Expression of the CTLA transcripts was induced under conditions (addition of IL-2) which led to the differentiation of non-cytotoxic thymocytes into cytotoxic cells (Fig. 1b); this, however, might reflect the differential growth on stimulation of a small subpopulation of precursor cells already making these transcripts. We therefore used PC60 hybridoma cells¹⁴ which are constitutive for growth but inducible for cytotoxicity; all three CTLA transcripts, which in non-induced PC60 cells were not or only barely detectable, appeared in PC60 cells when cytotoxicity was induced (Fig. 2a). Thus, in both thymocytes and hybridoma cells there was a correlation between induction of cytotoxicity and induction of the three CTLA transcripts.

We then wondered whether CTLA-1, which gave the clearest association (Fig. 1b) and induction (Fig. 2a) results, was homologous or identical to a previously sequenced molecule. The cDNA sequence that we obtained (Fig. 3) was not significantly homologous to any of the sequences in the Los Alamos Gene Bank. However, the translated protein sequence showed significant homology, but not identity, with known serine esterases (Fig. 3).

Southern patterns of liver DNA tested with probes from the three CTLA families showed a small number of bands (Fig. 2b), indicating that the corresponding genes are present as either one copy or a small number of copies per haploid genome. The respective patterns were the same for KB5C20 DNA (not shown), thus providing no detectable evidence for CTLA gene rearrangements in T cells. The chromosomal localization of the CTLA-1 gene was determined by in situ hybridization. Only one major binding site was found, in the D segment of mouse chromosome 14 (Fig. 4), interestingly in a region to which the T-cell receptor (TCR) α -chain gene has been mapped¹⁵. Experiments in progress, taking advantage of the cross-hybridization of CTLA-1 mouse probes to human DNA (not shown), suggest that CTLA-1 and TCR α genes might be co-localized on human chromosomes also.

Thus, we have detected three 'CTLA' genes whose transcription is induced preferentially or exclusively in cytotoxic T lymphocytes. A first question raised by these results is the nature of the CTLA protein products. That CTLA-1 is a cytotoxic T-cell-associated serine esterase is reminiscent of the detection

Fig. 3 The sequence of CTLA-1 cDNA and its protein translation. a, Sequencing strategy. The open reading frame of 741 nucleotides is indicated by a box on clone 7.1.2. b, cDNA sequence and the predicted amino-acid sequence. The open reading frame starts from the first ATG downstream of the stop codon at position 79. The 3'-untranslated region ends with the consensus polyadenylation signal AATAAA. There is a potential N-linked glycosylation site at Asn 70. The conceptual amino-acid sequence shows clustered homologies with trypsin-related serine-esterases, in particular around the serine-esterase active-site residues His, Asp and Ser (here at positions 64, 108 and 203, respectively). c, Alignment of the rat group-specific serine esterase sequence²⁸ with that of CTLA-1 from Ile 21 to Ile 240. The overall homology is 46%; identical stretches of sequence are boxed. Given the highly hydrophobic leader sequence in the NH2-terminal region, the potential site of cleavage of an activation peptide at Arg 15 or perhaps rather Lys 17, and the sequence homology with the initial residues of serine esterases, the putative active CTLA-1 protein would start at Ala 18 and therefore be 230 amino acids long.

Methods. KB5C20-derived single-stranded cDNA was synthesized as described in Table 1 (except that 4 mM Na-PP_i was included in the reaction), made double-stranded using RNase H (BRL), Pol I (Boehringer) and E. coli lipase (BRL) as described by Gubler and Hoffman²⁹ (except that the incubation was for 1 h at 12 °C and 1 h at 16 °C), tailed by TdT (NEN; 20 U μg⁻¹ in 50 μl of 200 mM KCaCo pH7.2, 1 mM CoCl₂, 500 μg ml⁻¹ bovine serum albumin, 5 μM dCTP for 40 min at 15 °C), and size-fractionated on 1.5% agarose. Slices corresponding to 1.2-1.6 kb were electroeluted and double-stranded cDNA annealed to the PstI site of dG-tailed PUC9 (NEN); transformation was as described in Table 1. The library was screened with the 450-bp PstI fragment of M41D12 which detected 10 clones, of which the 3 longest were analysed. Sequences were obtained by the dideoxy chain-termination method³⁰ for the two PstI fragments of M41D12 subcloned in M13, and by chemical cleavage³¹ following the strategy shown in α

in cytotoxic T cells of such enzymes at the protein level¹⁶. A comparison of partial sequences showed that CTLA-1 and the C11 clone described by Lobe *et al.*¹⁷ were almost identical; differences in the Northern patterns are being investigated. A second, key question—whether the CTLA products are actually involved in the mechanism of cytolysis—could be investigated by using anti-sense mRNA technology^{18,19}; the probable serine esterase activity of CTLA-1 suggests that it might have a profactor-activating role. Irrespective of the answers to these questions, it will be interesting to study the regulation of expression of the CTLA-1 gene in particular, which maps near the TCR α gene and is induced on differentiation into cytotoxic T-cells.

We thank C. Goridis, B. Jordan, B. Malissen and M. Pierres for advice and for reading of the manuscript, M. Pierres for the gift of T14.117 hybridoma cells. J. Sire and R. Sodoyer for advice and help in DNA sequencing, and M. Masson (Pasteur Institute) for computer searches in gene and protein sequence banks. We thank Dr Bleackley (Edmonton) for a crucial suggestion and for a comparison of a partial sequence. W. R. C. was supported by an Eleanor Roosevelt Fellowship and T.M.H. by the Founda-

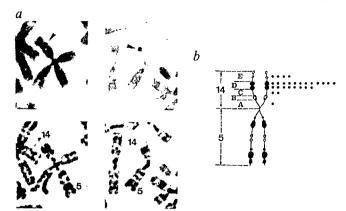

Fig. 4 Localization of the CTLA-1 gene to mouse chromosome 14 by in situ hybridization with the CTLA-1 probe C.1.1. a, Two partial WMP mouse metaphases, showing the specific site of hybridization to chromosome 14. Top, arrowheads indicate silver grains on Giemsa-stained chromosomes, after autoradiography. Bottom, chromosomes with silver grains were subsequently identified by R-banding. b, Diagram of WMP mouse Rb(5; 14) chromosome, indicating the distribution of labelled sites. In the 85 metaphases examined, there were 152 silver grains associated with chromosomes and 27 of these (17.7%) were localized on chromosome 14. The distribution of grains on this chromosome was not random: 74% of them mapped to the D band, with a maximum in the distal D3 part of this band (for banding nomenclature, see ref. 32).

Methods. In situ hybridizations with probe C.1.1 were done using metaphase spreads from a male WMP mouse in which all the autosomes (except 19) are in the form of metacentric robertsonian translocations (given by J. L. Guénet, Pasteur Institute, Paris). Con A-stimulated lymphocytes were cultured at 37 °C for 72 h, with 5-bromodeoxyuridine added for the final 7 h of culture (30 µg per ml of medium) to ensure a chromosomal R-banding of good quality. Total C.1.1. plasmid DNA was tritium-labelled by nick-translation to a specific activity of 10⁸ c.p.m. μ g⁻¹. The radiolabelled probe was hybridized to metaphase spreads at a final concentration of 2 μg per ml of hybridization solution, as described previously³³. After coating with nuclear track emulsion (Kodak NTB 2), the slides were exposed for 8 days at 4 °C, then developed. To avoid any slipping of silver grains during the banding procedure, chromosome spreads were first stained with buffered Giemsa solution and metaphases photographed. Then chromosome banding was realized by the fluorochrome-photolysis-Giemsa (FPG) method described by Camargo and Cervenka³⁴, and metaphases photographed again before analysis.

Voltage-gated Ca²⁺ entry into Paramecium linked to intraciliary increase in cyclic GMP

Joachim E. Schultz, Thomas Pohl & Susanne Klumpp

Pharmazeutisches Institut der Universität Tübingen, Morgenstelle 8, 7400 Tübingen, FRG

Inward Ca2+ currents exist in many excitable tissues and are linked to regulation of several cellular processes such as cyclic GMP formation 1-4. In *Paramecium*, a graded Ca²⁺/K⁺ action potential regulates swimming behaviour⁵⁻⁷. Voltage-gated Ca²⁺ channels localized in the excitable ciliary membrane^{8,9} conduct a depolarizing influx of Ca²⁺ and translate changes in membrane potential into a transient Ca²⁺ signal which triggers ciliary reversal, that is, backward swimming^{5,6}. A guanylate cyclase that is activated specifically by Ca²⁺ has already been characterized in the ciliary membrane¹⁰. By using behavioural mutants of *Paramecium* with reduced^{6,11,12} or exaggerated^{13,14} Ca²⁺ currents, we now demonstrate in an intact animal a direct link between the voltage-gated inward Ca2+ current and an elevation of cyclic GMP levels. Although the increased cyclic GMP level does not directly influence swimming behaviour, the combination of electrophysiology, biochemistry and genetics possible with Paramecium offers an opportunity of identifying the role of cyclic GMP levels in cell behaviour.

In several Paramecium strains, increasing the external K' concentration from 5 to 25 mM enhances ciliary Ca²⁺ permeability and causes a reversal of ciliary beating and consequently of the swimming direction⁵⁻⁷, a response similar to the avoidance displayed by Paramecium in adverse situations. This reversal lasts for 5-10 s and is mediated by the influx of Ca2+ into the cilia. In Paramecium tetraurelia wild-type 51s, the concentration of cyclic GMP increases from 3.8 to 5.5 pmol per mg protein 3-5 s after the addition of K^+ (Fig. 1a). The increase is moderate because the influx of Ca²⁺ leads to an inactivation of the Ca²⁺ channel within 5 ms^{5,15}. Consequently, the Ca²⁺-dependent guanylate cyclase is only briefly stimulated. Therefore, Ba2+ was used to increase the excitability of the Ca2+ channels by decreasing their rate of inactivation, thereby producing a more sustained (if somewhat slower) Ca²⁺ entry^{11,15,16}. Addition of 3 mM Ba²⁺ to wild-type Paramecium evoked a rapid, large and transient increase in cyclic GMP (Fig. 1b). The level of cyclic GMP attained a maximum 5-10s after stimulation and returned towards resting levels after 30 s. In the presence of Ba²⁺ the backward swimming response continued for ~60 s, indicating that the level of cyclic GMP does not directly control backward swimming. The effect of Ba²⁺ was specific, as 3 mM of Mg², Ca²⁺ or Sr²⁺ did not elicit the avoidance reaction or an increase in cyclic GMP. Moreover, the temperature dependence of the Ba²⁺-stimulated increase in cylcic GMP indicates that it is not the ion current itself but a subsequent step that is responsible for the effect. At 0 °C Ba²⁺ does not evoke an increase in cyclic

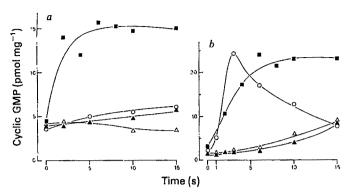

Fig. 1 Time-dependent increase in cyclic GMP concentrations in Paramecium tetraurelia wild-type 51 s (O), mutant pawn A (d4-94. △), double mutant pawn A/pawn B (▲) and mutant dancer (d4-614,) after a sudden increase in the concentration of K from 5 to 25 mM (a) or after addition of 3 mM Ba^{2+} (b). Methods. Early stationary cells grown in a bacterized hay infusion or in axenic complex medium²⁶ were collected by centrifugation at 250g, washed and equilibrated for 2 h at 40,000 cells ml (90,000 cells = 1 mg protein) in buffer containing $50 \,\mu\text{M}$ Ca²⁴ 5 mM K⁺, 10 mM MOPS pH 7.2. For stimulation, 250 µl of 40 mM K⁺ (a) or 6 mM BaCl₂ (b) in equilibration buffer were added to 250 µl of cells. Viability and behaviour were checked microscopically before and during the experiments. Incubations were stopped by adding perchloric acid (final concentration 1 M). Cyclic GMP was determined by radioimmunoassay using rabbit antibodies against cyclic GMP and 125I-iodinated 2-O'-succinyl-cyclic GMP-L-tyrosinylmethylester (for details see ref. 27). Cross-reactivity of the antibody with cyclic AMP was <5%. No cyclic GMP was found when samples were digested with phosphodiesterase isolated from pig brain before the assay. We did not detect cyclic GMP in the incubation medium nor did we observe differences in behaviour or cyclic GMP levels between cells grown in bacterized medium and those grown axenically.

GMP, although influx of Ca²⁺ does occur¹⁷; we attribute this effect to the lower activity of guanylate cyclase at this temperature.

Because both Ba2+ and Ca2+ compete for the inactivation site on the channel, the electrophysiological and behavioural effects of Ba2+ stimulation depend on the ratio of these cations in the medium^{16,18}. We established dose-response curves for Ba²⁺ in the presence of various Ca²⁺ concentrations. The ED₅₀ (50% effective dose) values for Ba²⁺-stimulated cyclic GMP levels in the presence of 3, 50 and 1,000 μ M Ca²⁺ were 0.1, 2 and 10 mM, respectively (Fig. 2), reflecting the competition between Ca² and Ba²⁺. Ba²⁺ elicited a concentration of cyclic GMP of only 15 pmol mg⁻¹ at 3 μ M Ca²⁺, compared with 28 pmol mg⁻¹ at an external Ca²⁺ concentration greater than 50 μ M (Fig. 2). Thus, low external Ca²⁺, leading to reduced Ca²⁺ influx^{16,19}, is correlated with considerably reduced production of intracellular cyclic GMP. Obviously, release of Ca²⁺ from intraciliary storage sites, if it occurred, was not involved in stimulating cyclic GMP production. Ba2+ itself does not stimulate guanylate cyclase activity in vitro²⁰ or antagonize Ca²⁺-mediated activation (Fig. 3). Importantly, the ED₅₀ of 9 μM Ca²⁺ for guanylate cyclase activation was not affected by the presence of 1 mM Ba²⁺ (Fig. 3). Thus we conclude that during an action potential Ca²⁺ enters the cilia with Ba²⁺ and directly stimulates ciliary guanylate cyclase.

Further evidence for a link between the inward Ca²⁺ current and intraciliary cyclic GMP production can be obtained by studying mutants possessing defects in ion conductances^{5-7,11,12}. 'Pawn' mutants lack voltage-gated Ca²⁺ channels^{11,12,16} and therefore cannot swim backwards. In agreement with electrophysiological and behavioural observations^{6,11,12}, we found that addition of 3 mM Ba²⁺ to pawn A or pawn A/pawn B cells did not stimulate cyclic GMP biosynthesis as in wild-type cells (Fig. 1b). 'Atalanta' mutants lack the axonemal response to Ca²⁺

despite having normal Ca2+ channels, so they are unable to reverse the direction of the ciliary beat and cannot swim backwards^{12,21}. Addition of 3 mM Ba²⁺ to atalanta cells produced an increase in the cyclic GMP concentration, from 4.6 pmol to 18.0 pmol mg⁻¹ after 10 s; as expected, this is comparable to the response of wild-type cells and reflects the fact that atalanta mutants have an intact inward Ca2+ current. Dancer mutants possess Ca²⁺ channels which inactivate more slowly and incompletely, resulting in enhanced inward Ca²⁺ currents^{13,14}. 'Dancer' cells display much longer periods of backward swimming when depolarized by K⁺ than wild-type Paramecium¹³. Thus, K⁺ stimulation should have a profound effect on the cyclic GMP content of dancer cells if the inward Ca2+ current is linked to intraciliary guanylate cyclase activation. Indeed, K+ evoked a fourfold increase in the concentration of cyclic GMP in dancer cells (Fig. 1a). In Ba²⁺-stimulated dancer cells, levels of cyclic GMP remained higher than those in comparably stimulated wild-type Paramecium (Fig. 1b). These observations are compatible with the defect in Ca^{2+} -channel inactivation in the dancer

The differences in cylic GMP production in vivo between wild-type and mutant Paramecium could be caused by different activities of guanylate cyclase. Therefore, enzyme activities were measured in cilia from all Paramecium strains used. The mean guanylate cyclase activity in wild-type and mutant preparations was 175 pmol per min per mg. We also investigated a possible involvement of phosphodiesterase in the regulation of cyclic GMP concentration. Using partially purified cyclic GMP phosphodiesterase from Paramecium, we found no effect of Ca²⁺ or Ba²⁺. Thus, inward flow of Ca²⁺ apparently stimulates intraciliary cyclic GMP production directly. Previously, we have shown by immunocytochemistry that cyclic GMP is predominantly localized in the cilia of Paramecium²²; this corroborates the link between voltage-gated Ca²⁺ influx and Ca²⁺-regulated guanylate cyclase.

Sophisticated control loops involving Ca²⁺ and cyclic nucleotides probably operate in most cells^{23,24}. In particular, hormonally stimulated production of cyclic GMP in metazoan tissues—for example, in brain¹, smooth muscle² and neuroblastoma cells³—has been demonstrated to depend on the presence of Ca²⁺. However, guanylate cyclases regulated by physiologically meaningful Ca²⁺ concentrations have not been found.

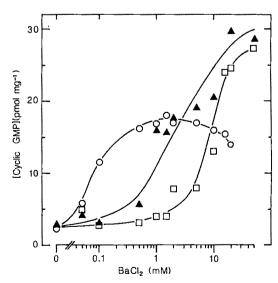

Fig. 2 Dose-response curves for Ba²⁺-stimulated cyclic GMP production in *Paramecium tetraurelia* wild-type 51 s in the presence of 3 (\bigcirc , n=5), 50 (\triangle , n=13) and 1,000 (\square , n=3) μ M Ca²⁺ in the equilibration and incubation buffer. Additions of Ba²⁺ were made to yield the indicated concentrations without affecting the concentration of other buffer constituents. Measurements were made 10 s after Ba²⁺ addition. For methods see Fig. 1 legend.

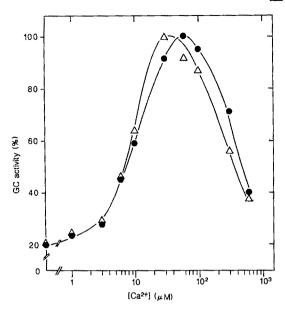

Fig. 3 Dose-response curve for Ca²⁺-stimulated guanylate cyclase (GC) in ciliary membranes from Paramecium. Membranes were washed with 60 µM EGTA followed by two washing steps with buffer to remove the chelator. All reagents were purified by treatment with Chelex. The remaining Ca2+ concentration was <1 µM. Activity was determined for various concentrations of Ca^{2+} in the absence (\bullet) or presence (\triangle) of 1 mM Ba²⁺. 100% activity corresponds to 1,560 pmol cyclic GMP per mg per min.

Here, we have demonstrated for the first time an unequivocal link between an inward Ca²⁺ current and enhanced cyclic GMP production.

In Paramecium the voltage-gated Ca2+ channels in the ciliary membrane serve as a mediator of all excitatory (that is, depolarizing) stimuli. In response to depolarizing receptor potentials, an action potential starts with a Ca²⁺ influx. Internally, Ca²⁺ has at least four effects: the inactivation of the Ca²⁻ channels within 5 ms, the activation of a Ca2+-dependent K+ efflux after 100 ms (ref. 25), the reversal of the direction of the ciliary power stroke, and the production of the second messenger cyclic GMP. That the electrophysiology, genetics and biochemistry of Paramecium can be studied in combination holds great promise for elucidating the molecular events of basic cellular processes controlled by cyclic GMP. At present, there are insufficient data to assign a common function for cyclic GMP in all cells but the functional relationship between cyclic GMP and Ca²⁺ in many tissues (for example in rod outer segments, which are phylogenetically a rudimentary cilium⁴) suggests that similarities in the regulation of cyclic GMP in different cellular systems will be found.

We thank Dr C. Kung (University of Wisconsin, Madison) for the Paramecium mutants. This work was supported by the Deutsche Forschungsgemeinschaft (SFB 323).
